## **ACKNOWLEDGEMENTS**

I wish to extend my heartfelt thanks to the following people for their aid completing this project. It would not have been possible without their help.

- To Dr. Amber Mosley- For taking me in and helping me make the best of a bad situation, and for being patient and kind when that was the most important thing in the world.
- To Dr. Mark Goebel- For being a constant source of guidance and mentorship throughout my time with the Biochemistry Department.
- To Dr. Andy Hudmon- For being a teacher and mentor, and also a friend.
- To my colleagues in the Mosley Lab, Whitney Smith-Kinnaman, Dr. Melanie Fox, Dr. Jerry Hunter, Sarah Peck, and Jose Victorino- For your help and instruction, as well as the use of your data.
- To my parents, Larry and Margaret Talbert- For your unwavering love and support throughout my life.
- To my sister, Dr. Erin Talbert- For your advice and mentorship, and for lending an ear when I needed one.

Eric A Talbert

CHANGES IN THE RPB3 INTERACTOME CAUSED BY THE DELETION OF RPB9  
IN *SACCHAROMYCES CEREVISIAE*

RNA Polymerase II (Pol II) is the primary actor in the transcription of mRNA from genes. Pol II is a complex composed of twelve protein subunits. This study focused on the changes in the interactome of Rpb3 in *S. cerevisiae* when the Pol II subunit Rpb9 is removed. Rpb3 is one of the core subunits of Pol II, and any significant changes to the Rpb3 interactome due to the loss of Rpb9 can be used to infer new information about Rpb9's role in the Pol II complex.

Rpb3 was pulled down using FLAG purification from both wild type and *rpb9Δ S. cerevisiae* cultures. Rpb3 and the proteins complexed with it were then analyzed using multi-dimensional protein identification technology (MudPIT), a form of liquid chromatography-mass spectrometry (LC-MS). This data was searched using the SEQUEST database search algorithm, and the results were further analyzed for likelihood of interaction using Significance Analysis of INteractome (SAINT), as well as for post-translational phosphorylation. Deletion of *rpb9* did not present any changes in Pol II phosphorylation however it did cause several changes in the interaction network. The *rpb9Δ* strain showed new interactions with Rtr1, Sen1, Vtc4, Pyc1, Tgl4, Sec61, Tfb2, Hfd1, Erv25, Rib4, Sla1, Ubp15, Bbc1, and Hxk1. The most prominent of these hits are Rtr1, an Rpb1 C-terminal domain phosphatase linked to transcription termination, and Sen1, an RNA/DNA nuclease that terminates transcription. In addition, this mutant showed no interaction with Mtd1, an interaction that is present in the wild type. In all cases, these hits should be considered fuel for future research, rather than conclusive evidence of novel interactions.

## **INTRODUCTION**

### **Genes and Gene Expression**

Transcription is the process of transforming genetic information stored within DNA into functional RNA molecules. These molecules perform a variety of roles within the cell, from structural and catalytic functions in ribosomes to blueprints for the synthesis of proteins. In all cases, however, transcription starts with a DNA template.

DNA is a polymer of nucleotides that serves as the primary information storage medium for living cells. DNA chains form a distinctive double-helix shape, with two phospho-sugar chains linked together by nitrogenous bases, forming a set of rungs on the twisted ladder of the DNA molecule. The sequence of these base pairs makes up a code that contains the actual genetic information stored within DNA (Watson, 1953).

A section of DNA that codes for a specific functional product is called a gene. Genes are the primary target of transcription. Genes can be divided into several sections based on function. Most notable of these is the transcribed region, which is the stretch of DNA that is copied during transcription. The first point of the transcribed region is called the transcription start site (TSS). Promoters are regions upstream of the TSS that interact directly or indirectly with the transcription complex, the group of proteins that, when bound together, perform transcription (Bayev, 1980). Most genes contain a core promoter region just upstream of the TSS. This is the binding site of the preinitiation complex, a grouping of proteins that work together to initiate transcription. Along with this core promoter, many promoter regions also contain enhancer elements that are bound by transcriptional activators, which are other proteins that encourage transcription of the gene (Bran, 1985).

Much of an organism's genome functions to regulate gene expression, or how and when genes are transcribed. In addition to transcriptional activators discussed above, some of this control comes from how DNA molecules are organized into structures called chromosomes. While prokaryote genomes are generally contained within one or a few chromosomes, eukaryotic organisms have multiple large, linear chromosomes. Because of their length, each chromosome is packed into multiple nucleosomes, genetic structures formed by winding a section of DNA around several proteins called histones. How a chromosome is packed into nucleosomes affects what DNA is available for transcription (Cedar, 1976).

Like DNA, RNA is a polymer of nucleotides. However, RNA is made up of ribonucleotide monomers, rather than the deoxyribonucleotide monomers of DNA. The presence of a second hydroxyl group in these monomers causes ribonucleotide monomers to form and break bonds more easily than deoxyribonucleotides. RNA polymers are therefore significantly less stable than DNA (Brenner, 1961).

Three forms of RNA, messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA), are directly responsible for converting the linear genetic information coded in DNA into proteins. Messenger RNA is transcribed from DNA and used as a working copy of the gene to produce the encoded protein (Brenner, 1961). Transfer RNA are RNAs with a looped structure that shuttle amino acids to growing peptides. Each tRNA binds to a specific amino acid. Correct amino acids are added to grown peptides using a three nucleotide sequence that complements the next three nucleotides in the mRNA template, called a codon. Translation, the process of translating the genetic code from an RNA transcript into a protein, occurs within specialized structures called ribosomes which form on mRNAs needing to be translated. tRNAs enter the ribosome and match to the bases of mRNA, delivering the needed amino acid during protein synthesis (Crick, 1968). Ribosomal RNA makes up the largest part of ribosomes, performing

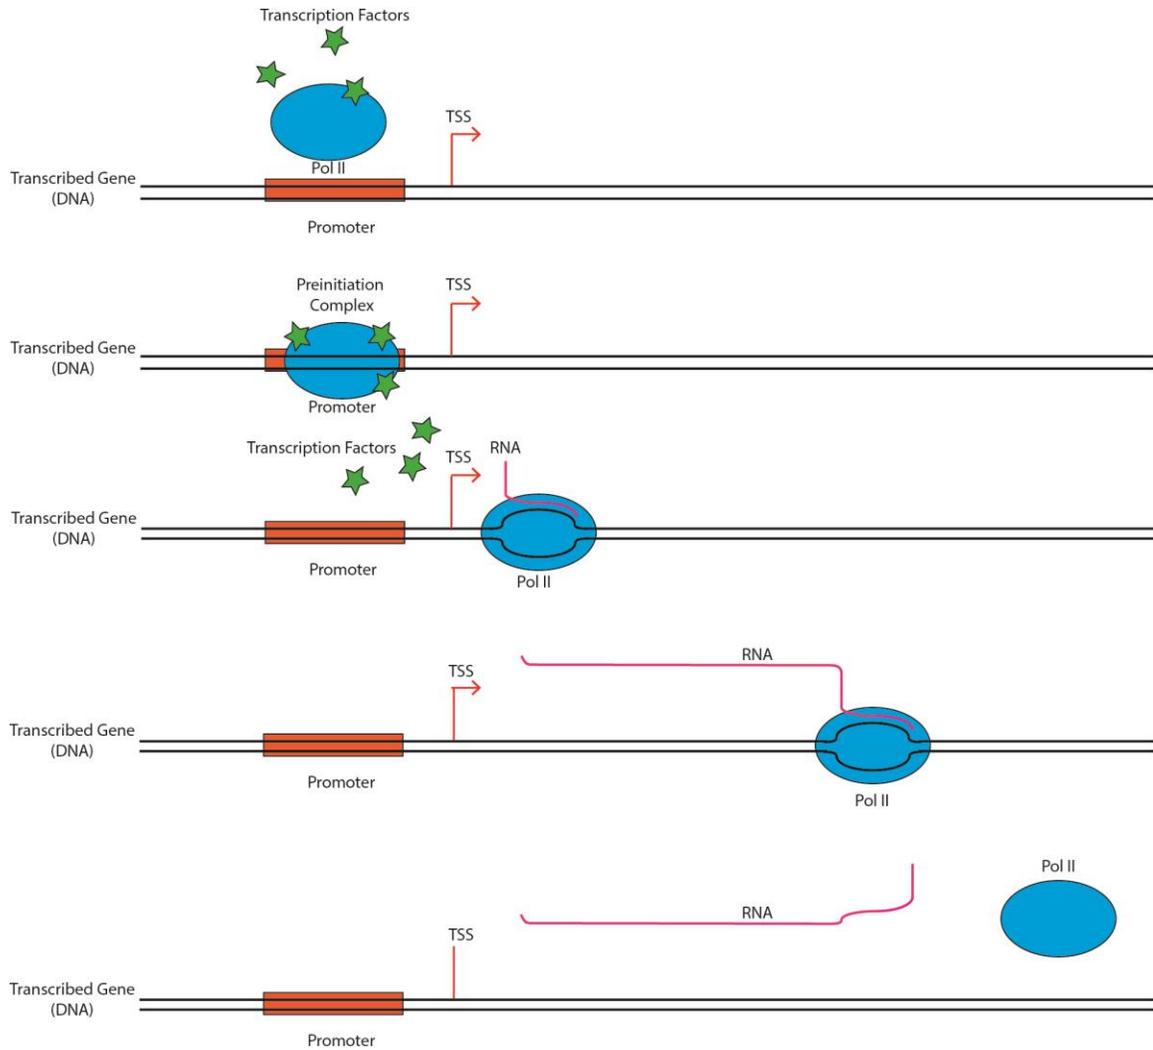

both catalytic and structural functions in the cell's protein synthesis machinery (Wimberley, 2000).

## **Transcription**

Transcription is the production of an RNA copy of a section of DNA. As discussed above, this is vital because although DNA is an extremely stable long-term storage molecule, unless that information can be extracted into a useful form, the information stored within genes cannot be expressed. Transcription allows the cell to make use of the instructions stored within its genome as needed.

Transcription is performed by a group of protein complexes called RNA polymerases. Ribonucleotides are matched by their bases to a DNA template and fused into a polymer chain, forming an RNA transcript (Sentenac, 1985). In prokaryotes, all transcription is handled by a single type of polymerase. However, in eukaryotes, different RNA polymerases transcribe different classes of RNA. In *S. cerevisiae*, the three polymerases are RNA polymerase I, II, and III. The majority of rRNA is transcribed by RNA polymerase I (Pol I). RNA polymerase II (Pol II), transcribes mRNA. RNA polymerase III (Pol III) synthesizes both tRNA and the 5S rRNA.

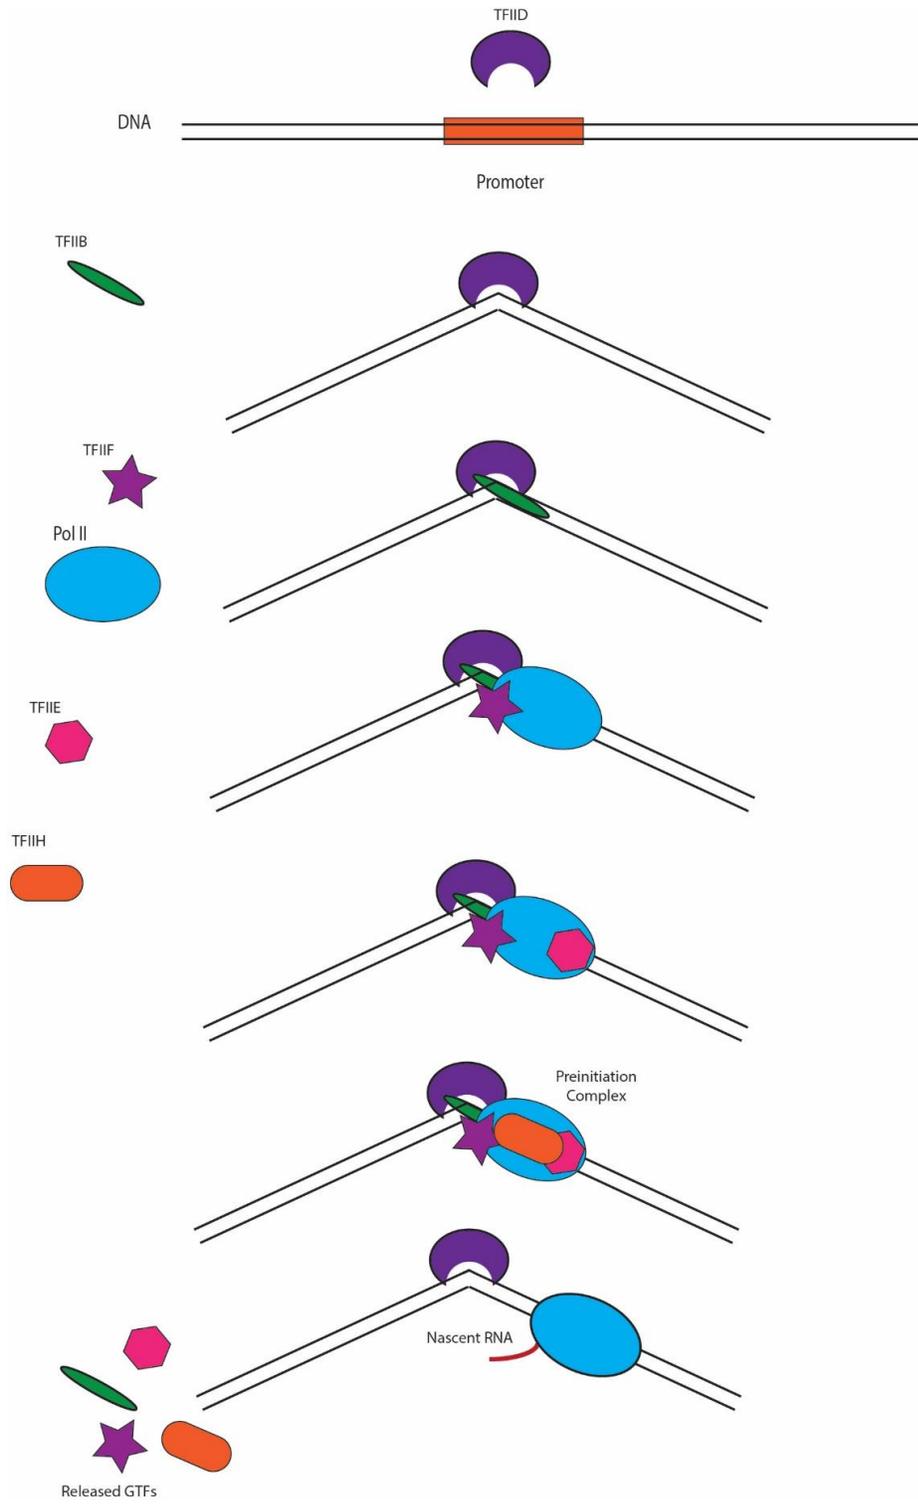

Pol II is the primary catalyst of mRNA synthesis, and thus the key link between DNA and protein synthesis. While Pol II contains all the machinery necessary to synthesize mRNA, the complex cannot perform transcription unaided (Myer, 1998). Numerous other proteins are involved in mRNA transcription. Transcription is an extremely complex process, and is not fully understood. However, the process can be broken down into three phases: initiation, elongation, and termination. A brief overview of mRNA transcription is presented in Figure 1.

**Figure 1: Transcription of Messenger RNA:** Transcription factors (green) bind Pol II (blue) and assist in finding and binding the core promoter (orange) of the transcribed gene (black). These transcription factors dissociate from the complex as Pol II adds the first few nucleotides to the nascent RNA molecule (magenta). Transcription transitions into elongation as Pol II continues to move along the gene adding nucleotides to the transcript. Eventually a termination sequence is received, and Pol II releases both the transcript and the transcribed gene.

Transcription initiation is the process of forming the preinitiation complex and preparing the gene for transcription. In most eukaryotic genes, this process begins when TATA binding protein (TBP), as part of the general transcription factor (GTF) TFIID, binds to the core promoter, a region adjacent to the TSS. GTFs are a class of protein complexes that help position RNA polymerases at the promoter and prepare the DNA for transcription. GTFs associated with Pol II use the nomenclature TFII.

After binding the core promoter, TFIID deforms DNA in a way that encourages strand separation, or melting. TFIIB then binds to TFIID and the promoter region, stabilizing the complex. Meanwhile, TFIIF binds and stabilizes Pol II, preparing the complex for recruitment to the promoter site by TFIIB. TFIIB then forms a bridge between the DNA-TFIID complex and Pol II. TFIIE binds to the nascent pre-initiation complex (PIC), stabilizing the PIC further and beginning the process of DNA melting. The 5'-3' DNA helicase TFIIH then binds to PIC. The helicase activity of TFIIH fully melts the TSS, allowing Pol II to begin transcription. Pol II matches free ribonucleotides the bases of the template DNA, fusing the monomers binding the first phosphate of the 5' end of the initial ribonucleotide to the hydroxyl group on the 3' end of the next monomer. After approximately 12 bases have been added to the nascent RNA molecule, the GTFs dissociate from the complex, and elongation begins (Woychik, 2002). The process of transcription initiation is detailed below in Figure 2.

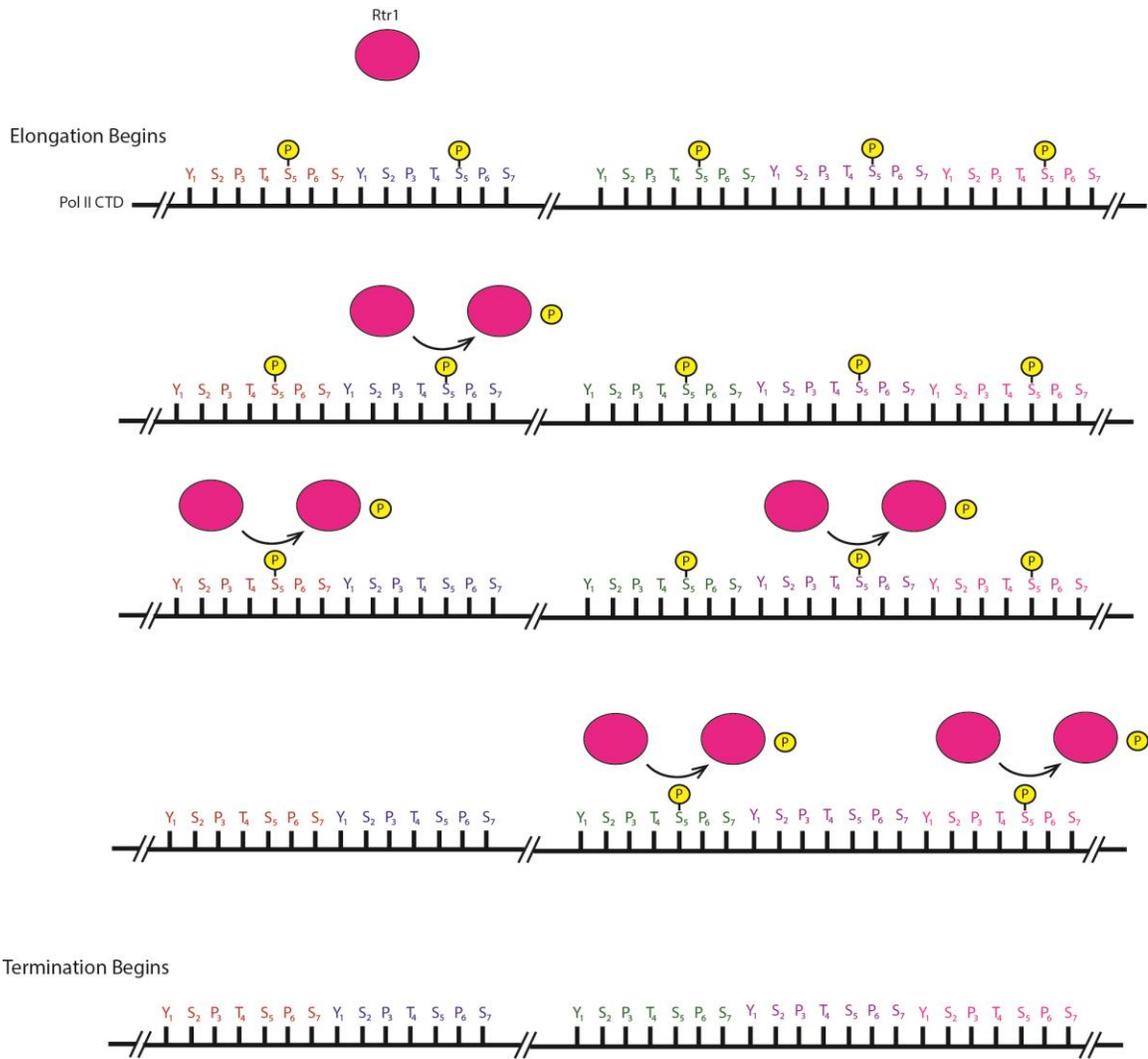

**Figure 2: Initiation of Messenger RNA Transcription:** TFIIID (purple) binds the core promoter (orange), deforming the DNA strand (black). TFIIIB (green) binds and stabilizes the TFIIID-DNA complex. TFIIIF (purple star) binds Pol II (blue), stabilizing the complex. TFIIIB binds Pol II, bridging gap the between promoter and Pol II. TFIIIE (pink) binds PIC, encourages DNA melting. TFIIH (orange) binds PIC, unwinding DNA to allow Pol II access to the coding strand. Pol II begins transcribing gene. After approximately 12 genes have been added, the GTFs dissociate from the PIC, leaving Pol II to begin elongation.

Elongation is the extension of the short mRNA transcript created during initiation. During this period the majority of bases are added to an mRNA molecule. Like initiation, elongation is regulated by a number of additional factors acting on Pol II. However, unlike initiation, these interactions are much more variable, and there is not a single clear model that can be applied to most elongation events. However, a recurring theme throughout transcription that continues in elongation is the modification of the C-terminal domain (CTD) of Rpb1, the largest subunit of Pol II. Rpb1 ends in a long, unstructured region of 25-52 repeats of the amino acid sequence  $Y_1S_2P_3T_4S_5P_6S_7$  (West, 1995). Post-translational modifications (PTMs), and especially phosphorylation of this region are responsible for modulating the activity of the protein and therefore regulating both transcription and cotranscriptional events such as mRNA processing (Corden, 1990).

Termination is the final step of transcription. Transcription is completed when the transcription complex reaches a termination site, a point in the gene that encourages Pol II to dissociate from the DNA template. However, termination can also occur prematurely for a number of reasons, including misincorporation of bases to the transcript, or because Pol II has reached an obstruction and cannot continue along the gene.

As with elongation, phosphorylation of the Rpb1 CTD plays a large role in regulation of termination. Several kinases and phosphatases target the CTD during elongation and termination. Most notable for this study is the phosphatase Rtr1. When elongation begins, the majority of the fifth serine of the CTD heptapeptide repeat (S-5) are phosphorylated by the kinase Kin28. As elongation continues S-5 phosphorylation becomes less common, and is almost nonexistent at the beginning of termination (Komarnitsky, 2000; Figure 3). Rtr1 is a phosphatase that targets S-5 during early RNAPII transcription elongation, removing the phosphate from serine 5 in the CTD repeats (Mosley, 2009).

**Figure 3: Changes in Phosphorylation State of Serine-5 of the RNA Polymerase II CTD Heptapeptide:** At the start of transcription elongation, the Pol II CTD heptapeptide repeat (black) is heavy phosphorylated (yell) at S-5. Rtr1 (magenta) removes these phosphate groups as elongation progresses. Termination becomes more likely as fewer S-5 residues are phosphorylated.

## RNA Polymerase II Function

Pol II is the evolutionarily conserved complex of proteins responsible for the transcription of mRNA. In yeast the Pol II complex contains 12 subunits and has a molecular weight of approximately 550 kDa (Cramer, 2002; Figure 4). As mentioned above, Pol II requires a number of additional factors to successfully perform transcription. Often these proteins complex with Pol II, and can be isolated from a cell lysate using an affinity pulldown protocol, allowing for the identification of interacting partners. Our chosen target for this affinity pulldown is Rpb3, a protein at the core of Pol II which has been used for purification of Pol II for multiple previous studies by our group (Mosley, 2009; Mosley, 2011; Mosley 2013).

Rpb3 is a core subunit of yeast Pol II. At 318 amino acids, Rpb3 is the third largest subunit of the complex, and has been shown to be part of a core DNA binding sub-assembly (Kimura, 1997). Rpb3 is vital for the overall stability of the Pol II complex, as it interacts with multiple other Pol II subunits (Kimura, 2000). Additionally, while some subunits are found in all three RNA polymerases, Rpb3 is unique to Pol II (Cramer, 2002). These traits make Rpb3 an excellent target to study the changes in Pol II's protein network when the complex is artificially disrupted, such as when Rpb9 is removed.

Rpb9 is a relatively small subunit of Pol II, at only 122 residues in yeast, and is highly conserved through eukaryotes. It is located at the tip of the "jaws" formed by Rpb1 and Rpb2, placing it near the active site of transcription (Cramer, 2000; Figure 4). While removal of Rpb9 from Pol II complex is nonlethal, this causes a significant reduction in the overall viability of the cells. Deletion of the *rpb9* gene causes both heat and cold sensitivity, and slowed growth even in ideal conditions (Woychik, 1991). Strains lacking *rpb9* also show significant inconsistencies in transcription start site selection (McKune, 1995). In addition, *rpb9* $\Delta$  cells show a much lower

tolerance for freeze-thaw stress, showing significantly slower growth after freezing at -25°C than WT after the same stress, even when normalized against unfrozen controls (Ando, 2007).

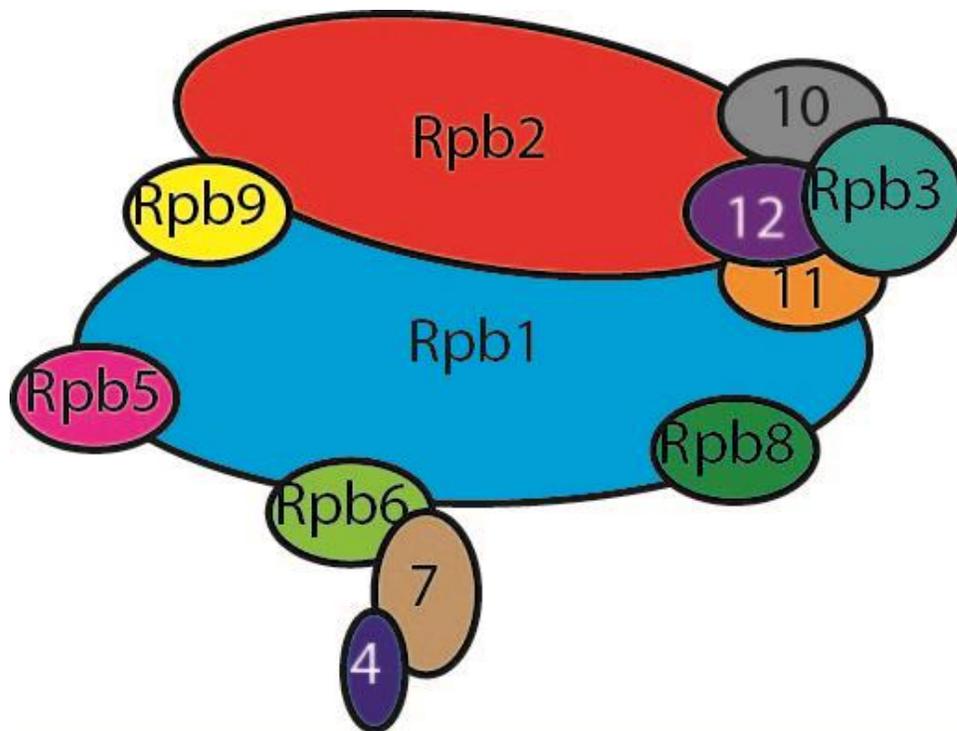

*In vitro* Rpb9, along with TFIIIS, was shown to be necessary for Pol II cleavage from sites of transcription arrest, ending a failed transcription event (Awrey, 1997). *In vivo*, *rpb9Δ* cells are sensitive to the drug 6-azauracil, (Hemming, 2000). This phenotype has previously been associated with transcription elongation defects in cells lacking *dst1*, the gene encoding TFIIIS (Exinger, 1992). Overexpression of *dst1* has also been shown to rescue 6-azauracil sensitivity in *rpb9Δ* cells, implying Rpb9 has a role in regulating elongation through an interaction with TFIIIS (Hemming, 2000).

In addition to a role in termination, Rpb9 is also active in the maintenance of Pol II transcription fidelity. A study used *can1*, which encodes permease that uptakes both arginine and the toxic arginine analogue canavanine, and a nonsense mutant *can1-100* that significantly reduced canavanine sensitivity, to measure the transcription fidelity effects of Rpb9. Deletion of *rpb9* showed a significant increase in canavanine sensitivity in the *can1-100* mutant, due to increased read-throughs of the premature stop codon (Nesser, 2006). This same study also showed that sequenced cDNA from *rpb9Δ* cells showed an error rate of  $2.0 \times 10^{-13}$  misincorporations per nucleotide, compared to  $1.4 \times 10^{-13}$  for WT cells. Rpb9 has since been shown to be required for two checkpoints events during transcription, one immediately following misincorporation of an NTP and another one nucleotide downstream of the incorrect NTP (Knippa, 2013).

Rpb9 has also been shown to play a role in the transcription coupled repair (TCR) of DNA. TCR in *S. cerevisiae* has been linked to Pol II stalling during transcription, such as might occur when the complex meets a lesion on the coding strand (Hanawalt, 2001). Rpb9 has been found

to mediate one of the two TCR pathways in yeast, a pathway primarily active within the coding region of genes (Li, 2002).

Rpb9 is non-essential in yeast. As such, deleting *rpb9* is a viable genetic perturbation. My central hypothesis for this work is that removing Rpb9 from the Pol II complex will force a number of compensations within the cell, significantly altering the Rpb3 interactome. The changes in this interactome should produce new inferences about Rpb9's role in transcription and the Pol II complex.

**Figure 4: Schematic of RNA Polymerase II Holoenzyme:** Note the position of Rpb9 between Rpb1 and Rpb2.

Rpb1	Largest subunit of Pol II. Part of central catalytic core. Activity of complex regulated by phosphorylation of CTD.
Rpb2	Subunit of Pol II. Part of central catalytic core.
Rpb3	Subunit of Pol II. Forms DNA binding structure and contributes to stability of Pol II complex.
Rpb4	Nonessential subunit of Pol II. Forms dimer with Rpb7 associated with temperature response.
Rpb5	Subunit found in all three RNA polymerases. Interacts with DNA during transcription.
Rpb6	Subunit found in all three RNA polymerases. Part of catalytic core.
Rpb7	Subunit of Pol II. Forms dimer with Rpb4 associated with temperature response.
Rpb8	Subunit found in all three RNA polymerases.
Rpb9	Nonessential subunit of Pol II. Associated with transcription fidelity and transcription coupled DNA repair.
Rpb10	Subunit found in all three RNA polymerases.
Rpb11	Subunit of Pol II. Forms part of central catalytic core.
Rpb12	Subunit found in all three RNA polymerases. Associated with DNA damage response.
TFIIB	Pol II transcription factor. Stabilizes TFIID-DNA complex, recruits Pol II to preinitiation complex.
TFIID	Pol II transcription factor. Binds and deforms core promoter DNA to initiate transcription.
TFIIE	Pol II transcription factor. Stabilizes transcription factor-Pol II preinitiation complex.
TFIIF	Pol II transcription factor. Stabilizes Pol II complex, helps to recruit Pol II to TFIIB.
TFIIH	Pol II transcription factor. DNA helicase that opens DNA to allow Pol II access to base pairs.
TBP	Binds core promoter in most transcription events. Part of the TFIID complex in mRNA transcription
Rtr1	Serine phosphatase that targets S-5 of the Rpb1 CTD heptapeptide repeat

**Table 1: Selected Actors in mRNA Transcription**

## **MATERIALS AND METHODS**

### **Bioinformatics**

The primary principle of bioinformatics is the use of high-throughput techniques to produce large volumes of data coupled with computational tools such as database searches that reduce the time necessary to analyze this data, allowing relatively quick turnaround times. It can be difficult to obtain high-resolution data from some of these methods. They are, however, perfect for narrowing general areas of interest into specific research questions. Bioinformatic tools are a tremendous aid in developing new lines of inquiry. The ability to analyze large volumes of data in a relatively short period of time means trends can be established with relatively little effort. Here we have analyzed interactions in the transcription machinery to discover novel avenues of investigation.

### **Affinity Purification**

Affinity purification is the use of a specific interaction to separate a desired material from a biochemical mixture. While there are several forms of this currently in use, tandem affinity purification (TAP) was used for this study. TAP makes use of a fusion protein made up of the protein of interest and an affinity tag. Chromatography is performed on a cell lysate from a culture expressing the fusion protein, with a resin made up of individual agarose beads, each bound to an antibody against the chosen epitope tag. This allows any proteins complexed with the fusion protein to be pulled down along with the bait from the protein mixture (Westermarck, 2013).

A FLAG tag was chosen for this investigation. FLAG is an eight peptide tag consisting of the sequence DYKDDDDK. FLAG was used because pull downs using this tag will extract both tightly bound proteins found in stable complexes and loosely bound proteins associated with dynamic

interactions. Using the traditional TAP tag, a calmodulin binding peptide, a two-step purification is required, which has been found to pull down only very tightly complexed proteins (Gavin, 2011).

### **Multidimensional Protein Identification Technology**

Multidimensional Protein Identification Technology (MudPIT) pairs liquid chromatography with tandem mass spectrometry to identify the components of a complex protein mixture (Wolters, 2001). MudPIT uses multi-phase high-pressure liquid chromatography (HPLC) columns to separate peptides to make certain they are ionized individually. Typically reverse-phase and strong cation exchange (SCX) materials are used, in either bi- or tri-phasic microcapillary columns (Florens, 2006).

Liquid chromatography, including HPLC, relies on the differences in polarity between the components of a mixture. This is accomplished by using a solid stationary phase packed into a column to initially capture the mixture. A mobile phase of a solvent is then run through the column. In reverse-phase chromatography used here, this mobile phase is initially a polar solvent, in this case water, while the stationary phase is hydrophobic. A second, less polar solvent, such as acetonitrile, is slowly exchanged for the first mobile phase. This gradient means that as the purification progresses, the mobile phase becomes less polar, causing progressively more hydrophobic compounds to elute off the column. In this way the most polar parts of a mixture are eluted first, while the most hydrophobic leave the column at the end of the gradient.

Treating a protein mixture with a protease creates shorter, more easily measured peptides. However, the resultant peptides are simply an amino acid chain with varied side chains, they have very similar hydrophobicities and will elute closely together. Traditionally increasing

separation on the column has been accomplished by increasing the column volume, usually column length. However, with extremely close eluting molecules this can require impractically long columns. Multi-phase columns containing two or more stationary phases allow for separation of molecules with very close hydrophobicity.

Reverse phase stationary phases consist of a highly packed, inert hydrophobic material. In practice, this means silica embedded with simple carbon molecules, usually C8 or C18. These materials allow for a slow enough flow of liquid through the column for molecules to adhere to the column during loading, and the hydrophobicity means the polar-to-non-polar gradient of the mobile phase to elute molecules of different polarity gradually.

SCX resins operate somewhat differently. These resins are embedded with a molecule containing an acidic group. In an aqueous environment, the negative charge of this group attracts molecules with a complementary charge. As the mobile phase becomes less polar, individual anions in the resin lose their charge, until eventually even perfectly complementary cations will lose attraction to the acidic groups and elute (Edelmann, 2011).

Once a specific peptide elutes from the column, the peptide is subjected to tandem mass spectrometry (MS/MS). Mass spectrometry uses the time it takes an ionized molecule to move a specific distance to judge its mass, and by inference its identity. Tandem mass spectrometry uses multiple mass spectrometry runs, interrupted by additional fragmentation of the analyte. This gives the masses of not only the initial molecule, but also a number of fragments that can be used to infer the mass of individual components. This is extremely useful for the identification of proteins, because the sequence of individual peptides can be inferred from this data.

## Peptide Spectra Analysis

A discussion of the algorithms used to identify proteins detected in MudPIT spectra is beyond this work, but an understanding of the fundamentals of this approach will be useful in reading this work. The mass of the original short peptide and all fragment ions are used to construct possible sequences for the precursor peptide. A protein database is then searched with an algorithm such as SEQUEST for sequences with a similar mass to the precursor. The matched sequences are further vetted using cross-correlation to compare the mass-to-charge ratio of the precursor to that of the sequences found in the database search (Eng, 1994).

In addition to identifying proteins, the data from MudPIT can be used to find post translational modifications (PTMs) of specific amino acids. Protein searches can be modified to search for the masses of commonly modified amino acids, such as phosphothreonine. In addition, phosphate and some other PTMs are often lost during the fragmentation process, causing a mass shift in the spectra of modified residues. This work utilized PhosphoRS, a piece of software that calculates the probability of phosphorylation at individual sites from MS/MS spectra.

## Significance Analysis of INTERactome

Significance Analysis of INTERactome (SAINT) is an open source method for examining protein-protein interactions. SAINT uses Bayesian analysis to score the likelihood of a data set illustrating a valid interaction between two proteins.

$$p(A|B) = p(B|A)p(A)/p(B)$$

Bayesian statistics is based on Baye's Theorem, listed above. Briefly, Baye's Theorem states that the probability that A is true, given that B is true, is equal to the probability that B is true,

given A is known to be true, multiplied by the dividend of the probability of A being true divided by the probability of B being true (Ellenburg, 2014). The details of the application of this theorem as applied in SAINT are beyond this work. A full explanation can be found in Choi, et. al (2006).

### **Isolation of Protein Fractions from FLAG Tagged *S. cerevisiae***

Two yeast strains isogenic to BY4741 were used in this study, a wild type strain and a knock out for *rpb9* from the Open Biosystems yeast knockout collection. Prior to this study, a sequence 3x-FLAG tag was inserted into the Rpb3 gene of both strains using a tagging cassette from the plasmid pBS1539. Both strains were streaked for isolation on separate yeast extract peptone dextrose (YPD, Table 2) media plates. These plates were grown overnight at room temperature. Single colonies from each strain were used to inoculate 35mL suspension cultures in YPD media, which were grown overnight at 30°C. 3L of YPD were inoculated from each of these starters. These cultures were likewise grown overnight at 30°C to final OD600s ranging from 2-4.

Cells from these cultures were harvested by centrifugation at 4,000 x g for 5 minutes at 4°C. These cell pellets were then resuspended in TAP lysis buffer (Table 2). Approximately 250 µL of glass beads were added to this lysis mixture, and the whole was vortexed intermittently at 4°C for 20 minutes to ensure mechanical lysis. The cell lysate was centrifuged at 12,000 x g for 60 minutes at 4°C to enrich for soluble proteins.

Yeast Extract Peptone Dextrose (YPD) Media (3L)	TAP Lysis Buffer (100 mL)
60g Yeast Extract	40mL 40mM HEPES-NaOH pH 7.5
30g Peptone	100mL 10% Glycerol
270mL milliQ Water	70mL 350mM NaCl
300mL sterile 20% Glucose	1 mL 0.1% Tween-20
	214.25 milliQ water

**Table 2: Reagents and Media**

### **Pulldown and Digestion of Protein Fraction**

The resulting protein fraction was mixed with 500 $\mu$ L of a FLAG resin and stirred overnight at 4°C. This suspension was transferred to a Bio-Rad Econoprep column and drained by gravity flow to remove unbound proteins. 60mL of TAP lysis buffer, followed by 25mL of 50mM ammonium bicarbonate (pH=8.0) were then run through the column to further wash the beads.

The beads containing the protein mixture of interest were resuspended in 50mM ammonium bicarbonate. Trypsin Gold was added to a final concentration of 0.0016  $\mu$ g/ $\mu$ L. The digest was shaken overnight at 37°C. Mixture was then transferred to a micro-spin column and centrifuged at 10,000 rpm for 2 minutes. 20 $\mu$ L of 90% formic acid was added to the flow through to stop digestion.

### **MudPIT Analyses**

MudPIT analysis was performed on the protein enriched fraction. The HPLC was performed by pressure loading 100  $\mu$ m silica microcapillary columns with 2  $\mu$ m reverse phase resin (C18 Aqua), 3  $\mu$ m strong cation exchange (Luna SCX) resin, and then an additional 8  $\mu$ m of reverse phase resin at the tip to form three-phase columns. Aliquots of approximately 125  $\mu$ L of the samples described above were pressure-loaded onto these columns, which were then equilibrated with a 5% acetonitrile, 0.1% formic acid solution.

Dual phase liquid chromatography, tandem mass spectrometry was then performed on the samples. Chromatographic separation was accomplished using a 10 step salt ladder of 50-350mM ammonium acetate preceding an organic gradient of 20-80% acetonitrile with a constant 0.1% formic acid content. Each step on the ladder was eluted into a ThermoFisher TLQ Velos for mass spectrometry. The ten most intense ions from this first MS were subjected to fragmentation by collision induced dissociation (CID) and MS/MS. Two technical replicates were performed for each of two separate biological replicates of this procedure, for a total of four replicates for each variable. Thermo Xcalibur software was used to automate the chromatographic separation, elution, and peptide fragmentation.

### **Analysis of MS/MS Spectra**

The RAW spectra files were searched with Thermo's Proteome Discoverer 1.4, using the SEQUEST search algorithm matching against the 2-27-2014 version of the Universal Protein Resource's (UniProt) *Saccharomyces cerevisiae* database to establish protein identities. The following search parameters were used: precursor mass tolerance = 1.4 dalton, fragment mass tolerance = 0.8 dalton, 2 missed cleavages were permitted, enzyme specificity was set to fully tryptic, minimum peptide length = 6 amino acids, static modifications = +57 daltons on cysteine (for all digestions that included TCEP and CAM treatment), dynamic modifications = +16 daltons on methionine and +80 daltons on serine, threonine, and tyrosine. After the initial database search, the spectra were further analyzed for individual residue phosphorylation and likelihood of interaction between Rpb3 and the other identified proteins.

The PhosphoRS node was used to identify individual phosphorylation sites. The spectra were searched using Proteome Discoverer. PhosphoRS identified signal loss on specific residues indicative of phosphorylation.

Confidence scores for the protein interactions were generated using the significance analysis of interactome (SAINT) algorithm. These calculations were performed using the Contaminant Repository for Affinity Purification (CRAPome) website ([www.crapome.org](http://www.crapome.org), Mellacheruvu, 2013) and control sets previously produced by the Mosley lab. The datasets were searched against the *S. cerevisiae* CRAPome 1.1 database to discount likely contaminants.

The results were broken into four categories based on SAINT value (SP) of each protein hit. Hits found to have  $SP > 0.90$  were considered near certain in this work, while  $SP = 0.75$  was the lower bound for high confidence interactions. Proteins scoring between  $SP < 0.75$  and  $SP > 0.25$  were considered to be inconclusive, while a score of  $SP \leq 0.25$  was considered to have no conclusive evidence of interaction. Near certain and high confidence protein hits were included in the protein network. These cutoffs were selected based on previous works (Smith-Kinnaman, 2014), as well as the distribution of scores within the data set.

## RESULTS

This study investigated the changes in interactions between the Pol II subunit Rpb3 and other proteins when the *RPB9* gene is deleted. Rpb3 was chosen for extraction because this protein is a core subunit of Pol II, and because Rpb3 performs a primarily structural role within the complex. Rpb9 is a nonessential subunit, but has been linked to a variety of processes involving transcription, making this protein an ideal variable to study the interaction network of Rpb3, and by extension the interactions of Pol II.

Rpb3 and its interactors were pulled down from both wild type and *rpb9Δ* cells, and were then analyzed using MudPIT. By using *rpb9Δ* cells, we can determine which interactors are specific to the Rpb9 protein as well as proteins interacting with Pol II that are potential attempts to compensate for the deletion. Pull down was accomplished using the FLAG octopeptide, as the single purification method used with this epitope tag has been shown to extract both tightly bound proteins found in stable complexes and loosely bound proteins associated with more dynamic interactions (Gavin, 2011). Spectra resulting from this MS/MS study were analyzed to establish individual peptide sequences. These sequences were analyzed using the SEQUEST algorithm to match the peptide sequences to specific proteins. The identified spectra were then analyzed using phospho-RS to determine likely points of phosphorylation, and using SAINT to determine the likelihood that the identified protein interacts with Rpb3.

### Phosphorylation Analysis

First, the spectra gathered were analyzed for phosphorylation. PhosphRS was used to calculate the probability of phosphorylation for each peptide. This was accomplished by examining amino acids known to be regularly phosphorylated, primarily serine, threonine, and tyrosine for a distinct mass shift. Phosphorylation can be assumed if one of these amino acids

shows an 80 dalton mass shift. Of the phosphorylation sites identified, all were found in both the wild type and *rpb9Δ* PolII subunits. As such, there is no conclusive evidence for a unique phosphorylation pattern caused by the absence of Rpb9.

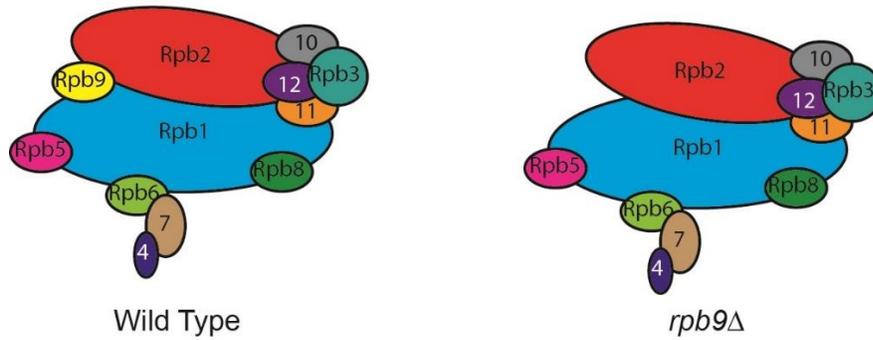

### **SAINT Analysis of Pol II**

Identified spectra were also analyzed using the SAINT algorithm to correlate abundance of spectra with the likelihood of an interaction with the bait protein Rpb3. The resultant SAINT probabilities (SP) ranged from 0 to 1, with a score of 1 meaning an almost certain interaction. A score of 0.5 means there is a 50% probability the proteins interact and an equal probability that the protein was pulled down by chance.

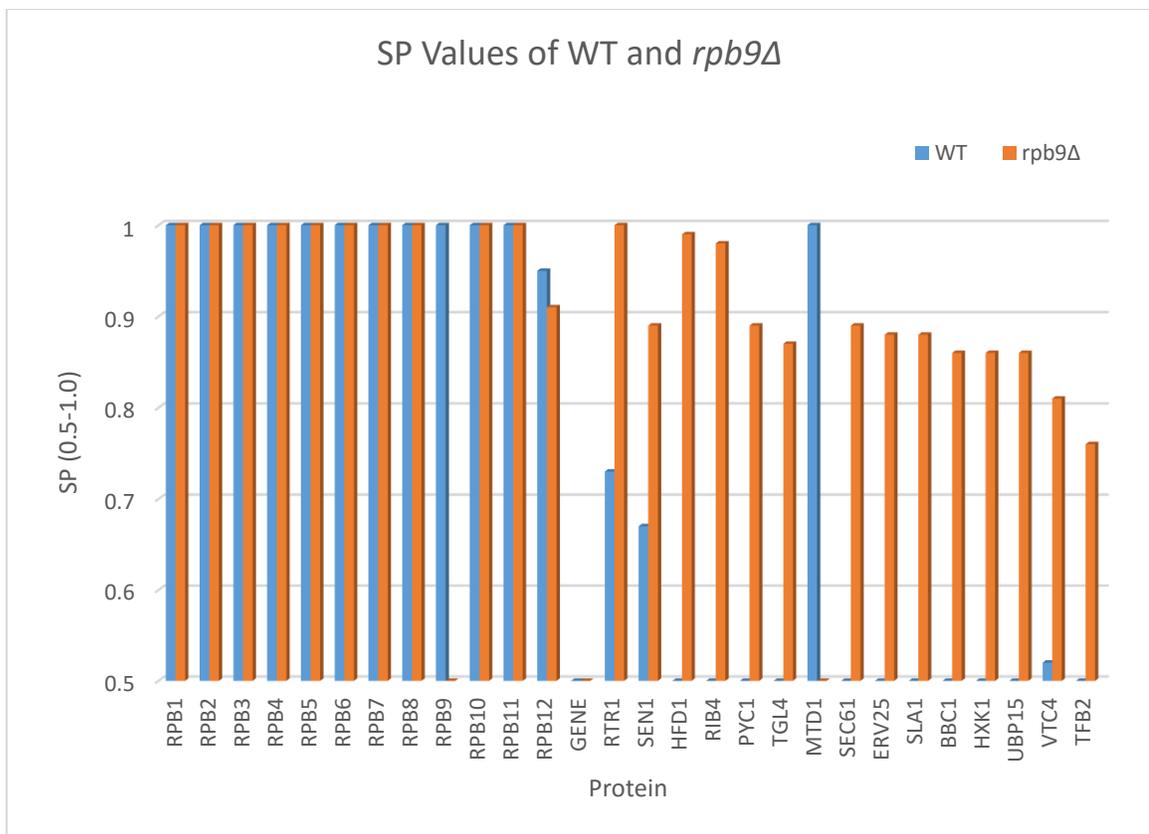

Protein identifications were organized into four categories based on SP as described above in the Methods section. Identifications with  $SP \geq 0.9$  are considered to have a near certain interaction. Identifications scoring between  $0.9 > SP = 0.75$  are classified as high confidence interactions. Proteins identifications between  $SP < 0.75$  and  $SP > 0.25$  were considered to be inconclusive, while scores of  $SP \leq 0.25$  are considered to have no conclusive evidence of interaction. These relatively strict thresholds were chosen to avoid false positives due to background, as hits scoring as low as  $SP = 0.60$  could reasonably be investigated if other evidence indicated a likely interaction. See Appendix 1 for the full set of SAINT scores.

No peptides matching Rpb9 were found in the *rpb9Δ* strain, confirming the deletion. It can be inferred that Rpb9 does not affect Rpb3's interaction with other members of the complex, and furthermore that Rpb9 connects to the complex as an isolated, single protein subunit (Figure 5). This is consistent with currently available structures (Sainsbury, 2013). The slight dip in the SP of Rpb12 compared to the rest of the complex also bears explaining. This result is an artifact of a bias in the SAINT algorithm. Rpb12 is only 70 amino acids, significantly shorter than

most of the subunits, but still of equal size to Rpb10 (Carles, 1991). However, Rpb12 has only one uniquely identifiable, or proteotypic, peptide, compared to Rpb10's three (Mosley, 2011). This means that fewer peptides will be identified as definitely from this protein, and therefore the SP will be lower than the actual concentration of the protein would suggest.

**Figure 5: Schematics of Wild Type and *rpb9Δ* Pol II.** Only Rpb9 is missing from the deletion strain in this dataset, implying it is an isolated subunit.

**Figure 6: SP Values of WT and *rpb9Δ* strains for Pol II Subunits and Significant Hits.** Fifteen protein hits not belonging to the Pol II complex were considered significant. Only Rpb9 is absent from the Pol II complex of the deletion strain, indicating a successful knockout. Also note the slightly lowered SPs of Rpb12, caused by a lack of proteolytic sequences within that protein.

## Significant Hits from SAINT Analysis

Fourteen proteins were found to have a higher SP in *rpb9Δ* than in wild type. Additionally one protein, Mtd1, was shown to drop from a near certain interaction to no conclusive evidence for interaction with Rpb3 when Rpb9 was removed. A brief discussion of each of these proteins follows. Importantly, several of these proteins have no previously documented interactions with Pol II. While it is possible these hits represent novel interactions, it is also possible they were pulled down complexed to another protein. This is noted where it seems likely, based on existing literature and our dataset.

Regulator of Transcription 1 (Rtr1) scored as inconclusive (SP=0.58) in WT, but this score increased to high confidence (SP=0.75) in the *rpb9Δ* strain. Rtr1 has been shown to physically interact with Rpb3 in multiple studies (Gavin, 2006; Mosley, 2009). Interestingly, Rtr1 also appears to have a genetic interaction with Rpb9, as *rpb9* has been shown to be a high copy suppressor of *rtr1Δ* temperature sensitivity (Gibney, 2008).

Splicing Endonuclease 1 (Sen 1), an ATP-dependent RNA/DNA helicase, scored as inconclusive (SP=0.67) in WT, but scored as high confidence (SP=0.89) in *rpb9Δ*. No direct interactions between Sen1 and Rpb3 or Rpb9 have been documented. However, Sen1 has been shown to interact physically with Rpb1, the largest subunit of Pol II (Ursic, 2004). Therefore, I hypothesize that Sen1 is pulled down bound to Rpb1, and the changes witnessed were the result of altered transcription activity, rather than any specific effects that the deletion of *rpb9* has on the ability of Sen1 to complex with Rpb3.

Homolog of fatty aldehyde dehydrogenase (Hfd1) is a hexadecenal dehydrogenase. Hfd1 was not present in the WT sample (SP=0), but scored as near certain (SP=0.99) in *Δrpb9*. No physical interactions with the Pol II complex have been documented previously. It is possible,

then, that Hfd1 was pulled down due to an interaction with an accessory protein of Pol II.

However, no proteins with documented interactions with both Pol II and Hfd1 were found in this dataset. It is probable that hit represents a novel interaction.

Riboflavin biosynthesis protein 4 (Rib4) is lumazine synthase. Like Hfd1, Rib4 was not present in the WT sample (SP=0), but showed a near certain interaction of SP=0.98 in *Δrpb9*. No physical interactions between Rib4 and Pol II have been documented. The most likely link between Rib4 and transcription is the protein ubiquitin specific protease 3 (Ubp3). Ubp3 has documented physical interactions with both Rib4 and the Rpb1 and Rpb2 subunits of Pol II (Kvint, 2008; Ossareh-Nazari, 2010). While Ubp3 scored as inconclusive in our dataset, Ubp3's SP score increased from SP=0.49 in WT cells to SP=0.64 in *rpb9Δ* cells. SP=0.64 is below the threshold for a high-confidence result, but is significantly above SP=0.5, and therefore an interaction between Rpb3 and Ubp3 is still possible.

Pyruvate carboxylase 1 (Pyc1) showed an increase in SP in the absence of Rpb9, going from an inconclusive result (SP=0.5) in WT cells to a high confidence score (SP=0.89) in *Δrpb9* cells. Pyc1 shows no direct interactions with the Pol II complex. In this case, the only probable link is Ess1, which has been shown to physically interact with Rpb1, Rpb2, and Rpb3 (Ho, 2002; Krogan, 2006; Ma, 2012). While Ess1 was not present in the WT samples, and has an SP of only 0.44 in *rpb9Δ*, Ess1 is the only protein with documented physical interactions to both the Pol II complex and Pyc1 present in our data set. It is possible, then, that Ess1 linked Pyc1 to Pol II during our extraction.

Triacylglycerol lipase 4 (Tgl4) was not present in the wild type sample (SP=0), but scored as high confidence (SP=0.87) in *Δrpb9*. No direct links to Pol II have been documented. Strong interactions have been documented with the cyclin dependent kinase Cdc28 and core histones

Hht1 and Hht2 (Gilmore, 2012; Ubersax, 2003). These proteins have numerous documented interactions with Pol II as well (Cosma, 2001; Chymkowitch, 2012; Smolle, 2012). However, none of these proteins had a significant presence in this dataset. This finding therefore may represent a novel interaction.

Hexokinase isoenzyme 1 (Hxk1) showed a high confidence interaction with Rpb3 only in *rpb9Δ* cells (SP=0.86), while there was no conclusive evidence for an interaction (SP=0.05) in WT cells. There are no documented interactions between Pol II and Hxk1. Two proteins in our data set, Dhh1 and Pat1, have documented interactions with Pol II and Hxk1 (Mitchell, 2013). However, Dhh1 scored SP=0.01 in WT and SP=0.22 in *rpb9Δ*, while Pat1 scored SP=0.00 in WT and SP=0.18 in *rpb9Δ*. Thus, there is then no evidence for interaction between Rpb3 and these proteins in our dataset, and Hxk1's scoring likely represents a novel interaction.

Secretory protein 61 (Sec61) scored as inconclusive in WT (SP=0.42), but scored as high confidence in *Δrpb9* (SP=0.89). There is no documentation for physical interactions between Sec61 and Pol II. She2 has been documented to interact with both Rpb1 and Sec 61 (Shen, 2010). However, in our dataset, She2 is present only in the *Δrpb9* sample, and scored as inconclusive there (SP=0.33). It is a possible link to Pol II, but it is more likely that the presence of Sec61 in our dataset represents a newly documented interaction.

ER vesicle protein 25 (Erv25) showed an increase in SP after deletion of *rpb9*, going from an inconclusive (SP=0.45) to a high confidence score (SP=0.88). There are no known physical interactions between Erv25 and Pol II. Erg5, found in this dataset, has been shown to interact with both Rpb5 and Erv25 (Tarassov, 2008). Erg5 scored inconclusively in SAINT, with WT SP=0.25 and *rpb9Δ* SP=0.44. However, it is still possible that Erv25 was pulled down bound to Erg5 and is linked to the Pol II complex through this interaction.

Sla1 show no interaction (SP=0) in WT, and a high confidence score (SP=0.88) in  $\Delta rpb9$ . Sla1 is a cytoskeletal protein binding protein. No physical interactions have been shown with Rpb3. However, Sla1 had been shown to interact physically with Sen1 (Tonikian, 2009). As mentioned above, Sen1 has documented interactions with Rpb3, and scored significantly in the *rpb9* $\Delta$  dataset.

Bbc1 showed no conclusive evidence of interaction in WT (SP=0.2), and a high confidence score in  $\Delta rpb9$  (SP=0.86). There are no documented physical interactions between Bbc1 and Pol II, and no potential links between Rpb3 and Bbc1 were found in our dataset. This hit likely indicates a novel interaction.

Ubiquitin-specific protease 15 (Ubp15) showed no interaction with Rpb3 in WT (SP=0), and a high confidence score (SP=0.86) in  $\Delta rpb9$ . Current literature shows no interactions between Ubp15 and Pol II. The protein Ssd1 has shown interactions with both Ubp15 and Rpb1 (Krogan, 2006; Phatnani, 2004). Ssd1 scored as SP=0.05 in WT and SP=0.57 in *rpb9* $\Delta$ . While this is not considered a significant hit by our criteria, it is still a possible link between Ubp15 and Rpb3.

Vacuolar transporter chaperone 4 (Vtc4) scored as inconclusive in WT (SP=0.52), and as high confidence in  $\Delta rpb9$  (SP=0.81). There are no previously documented physical interactions between Vtc4 and Pol II, and no proteins present in the dataset that could act as a link between the two. It is probable this hit is a novel interaction.

Transcription factor B subunit 2 (Tfb2) is a subunit of TFIIH essential for global genomic nucleotide excision repair (Feaver, 1997). Tfb2 showed no interaction in WT (SP=0), and a high confidence score in  $\Delta rpb9$  (SP=0.76). Physical interactions have been documented between Tfb2 and Rpb7 (Duran, 2013). As a transcription factor, Tfb2 would be expected to interact with the Pol II complex.

Unlike the other protein hits, methylene tetrahydrofolate dehydrogenase (Mtd1) showed a loss of interaction with Rpb3 when Rpb9 was removed from the system, going from a near certain result (SP=1) to showing no conclusive interaction (SP=0.33). There are no previously documented physical interactions between Mtd1 and Pol II, and no proteins present in the dataset that could act as a link between the two. Therefore, this is likely a novel interaction in the WT cells. Why this has not been found in previous investigations of Rpb3 is unclear.

## DISCUSSION

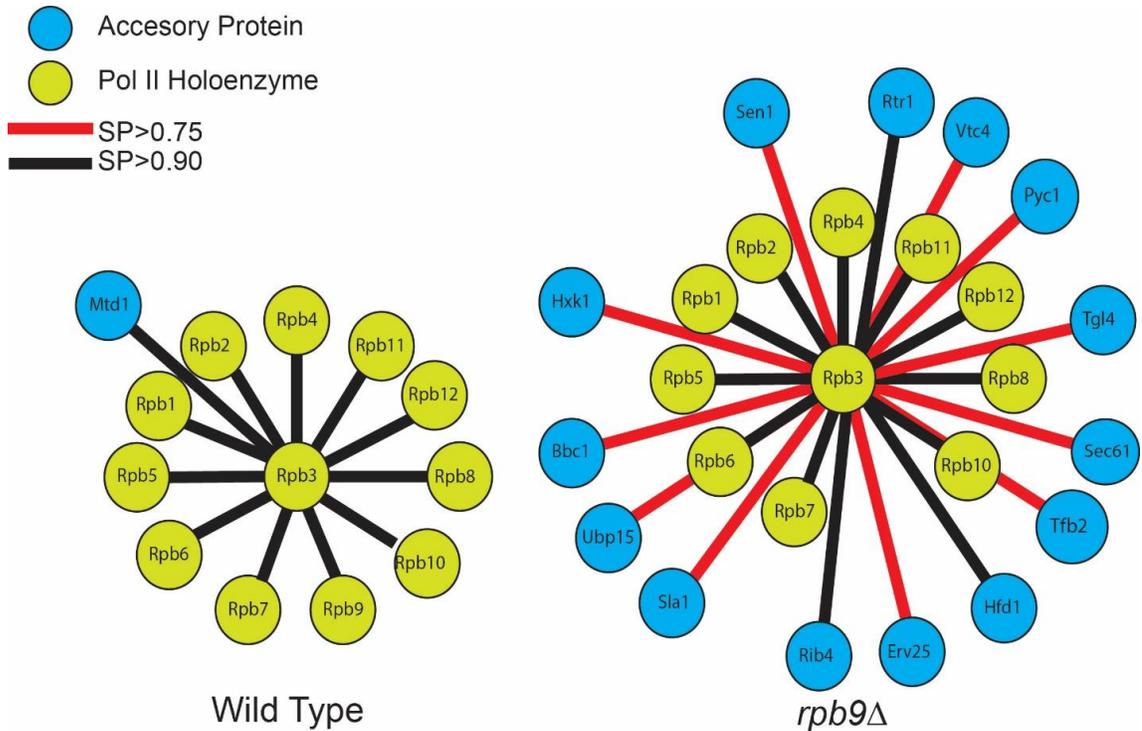

The interactome of Rpb3 provides a useful window for studying transcription and the function of Pol II. Rpb3 is one of the core subunits of Pol II, and interacts with a large number of proteins outside of the Pol II complex. Rpb3 is also found exclusively in Pol II, unlike several other subunits of the complex.

*RPB9* was chosen for deletion because this gene encodes a non-essential subunit of Pol II, and deletion of *rpb9* has been shown to increase the rate of transcription error (Nesser, 2006). Rpb9 causes transcription to pause when a mismatched nucleotide is incorporated, both at the initial incorporation and after a second nucleotide is added. This pausing allows the proofreading mechanisms of transcription time to act on the error. The Pol II complex has shown inherent nucleotide excision activity, but this activity is enhanced by the transcription factor TFIIS. The effect of TFIIS on Pol II is reduced when the Pol II complex lacks Rpb9, in addition to the loss of pausing caused by the absence of Rpb9 (Knippa, 2013). Once the elongation complex has passed a nucleotide mismatch, it becomes much more difficult for the cell to correct the error. In many cases, transcription is simply ended prematurely, and the error-containing transcript is removed from the complex.

As detailed previously, protein hits were classified by SP. Hits with  $SP \geq 0.9$  are considered to have a near certain interaction. Hits scoring  $0.9 > SP \geq 0.75$  are classified as high confidence interactions. Proteins scoring  $0.75 > SP > 0.25$  were considered to be inconclusive, and hits with  $SP < 0.25$  were considered to have no evidence for interaction.

Deletion of *rpb9* caused several changes to the protein network (Figure 7). These results are not by themselves conclusive, and are offered primarily as leads for future investigations. However, suppositions can be made as to the reason for these changes in protein interactions,

and have been offered where current literature supports them. A diverse group of protein hits were produced, but broadly they can be divided by function: proteins involved transcription termination, metabolic proteins, proteins associated with transport in the Endoplasmic Reticulum, cytoskeletal proteins, proteins associated with DNA replication signaling, vacuolar transport proteins, and proteins involved with DNA repair.

**Figure 7: Changes in the Protein Network of Rpb3 between Wild Type and *rpb9Δ* Cells.** A number of compensations were exhibited with the deletion of RPB9.

Rtr1 and Sen1 are active in transcription elongation and Sen1 has a well described role in Pol II termination, and the presence of these two proteins is arguably the most significant result of this study. The increase in the interaction both these proteins show with Pol II after *rpb9* deletion could indicate an increased rate of transcript termination during early PolIII elongation.

Rtr1 is a phosphatase that targets the CTD of Rpb1 (Mosley, 2009). The CTD region of the Pol II transcription complex is composed of a repeated heptapeptide motif with the sequence  $Y_1S_2P_3T_4S_5P_6S_7$  (Corden, 1990). Modification of this region controls much of transcription. Elongation generally begins with a high level phosphorylation of the fifth serine (S5-P). As elongation continues, S5-P becomes less common, and phosphorylation of the second serine (S2-P) becomes more prevalent (Komarnitsky, 2000). ChIP studies have shown that Rtr1 is most active early in transcription (Mosley, 2009).

When *rpb9* is deleted, Rtr1's interaction score with Rpb3 increased from inconclusive in WT (SP=0.73) to near certain in *rpb9Δ* (SP=1). This change could be caused by an increased amount of early Pol II stalling during elongation, due to a loss of Rpb9's error correction activity or TCR mediation. The reverse has been previously documented, as *rpb9* overexpression has been shown to rescue the heat sensitivity of *rtr1Δ* strains (Gibney, 2008).

Sen1 is likewise important for termination and could be involved in truncation of error-containing transcripts. Sen1 is an RNA/DNA helicase that separates developing RNA strands from DNA templates, disrupting the elongation complex and terminating transcription (Porrua, 2013). This termination has been found to attenuate transcription of specific genes, notably *NRD1*, *HRP1*, and *IMD2*. All three of these genes share a conserved TATA box sequence, and Steinmetz (2006) has suggested that these Sen1 regulated genes may assemble a unique preinitiation complex. Sen1 interaction scores with Rpb3 increased from inconclusive (SP=0.63) to high confidence (SP=0.89) with the deletion of *rpb9*. Elevated levels of Sen1 interaction with Pol II could indicate an increased rate of transcription termination during early Pol II transcription. As mentioned above, Sen1 has been shown to interact with Rpb1 (Ursic, 2004). It

is therefore likely this result indicates an increase in the direct interaction between Rpb1 and Sen1 in the absence of Rpb9, rather than a novel interaction with Rpb3. However, it is also possible that we have identified Rpb9 as a novel regulator of Sen1 binding to Pol II.

Hfd1, Rib4, Pyc1, Tgl4, and Mtd1 are all proteins associated with the metabolism of specific molecules. Also notable is that none of these proteins have been shown to interact with the Pol II complex previously. Unique to this study, Mtd1 showed a loss of interaction after the deletion of *RPB9*. Hfd1, Rib4, Pyc1, and Tgl4 all only showed interactions in *rpb9Δ* cells.

Hfd1 showed a dramatic increase in SP in *rpb9Δ* cells compared to WT, moving from a score of no evidence of interaction (SP=0) to one of near certain interaction (SP=0.99). An aldehyde dehydrogenase, Hfd1 is involved in the breakdown of sphingosine-1-P, and is therefore crucial to the metabolism of sphingolipids (Zahedi, 2006). A defect in the human homologue of Hfd1, ALDH3A2, is responsible for Sjögren–Larsson syndrome, a rare congenital condition that causes scaly skin, neurological defects, and mild to moderate cognitive impairment (Nakahara, 2012). ALDH3A2 is also integral to the oxidative stress response, as this enzyme metabolizes aldehydes produced by reactive oxygen species (Vasiliou, 2000). It is possible Hfd1 is performing a similar role in yeast. However, the protein is found primarily on the mitochondrial membrane (Zahedi, 2006). There is little evidence for Hfd1's presence in the nucleus, and so how this protein interacts with Pol II remains obscure.

Like Hfd1, when *rpb9* was deleted Rib4's SP increased from no evidence of interaction (SP=0) to a near certain interaction (SP=0.98). Rib4 is a lumazine synthase, involved in riboflavin synthesis. Rib4 catalyzes the synthesis of 6,7-dimethyl-8-ribityllumazine, the direct precursor of riboflavin (Garcia-Ramirez, 1995). *Ashbya gossypii*, a close relative of *S. cerevisiae*, has been shown to overproduce riboflavin under stress (Schlösser, 2007). This behavior has not been

documented in wild type *S. cerevisiae*. However, as riboflavin acts as a UV protectant, it is possible this is compensation for the loss of Rpb9. Loss of Rpb9 causes increased transcription errors as well as a decrease in transcription coupled DNA repair. As such, protecting the genome from further damage due to UV light would be vital to the continued health of the organism. This model does not explain why Rib4 is found interacting with the Pol II complex.

Rib4 has no documented interactions with the Pol II complex. Rib4 has previously been shown to interact with Ubp3, a ubiquitin-specific protease that has also been shown to interact with the Rpb1 and Rpb2 subunits of Pol II (Kvint, 2008; Ossareh-Nazari, 2010). Like Rib4, Ubp3 has been shown to increase in abundance in response to DNA replication stress (Tkach, 2012). Also like Rib4, Ubp3's SP score increased in *rpb9Δ* cells (SP=0.64) as compared to WT cells (SP=0.49). It is possible that Ubp3 interacts with both the transcription machinery and Rib4 in the absence of Rpb9 as a form of compensation for the loss of transcription-coupled DNA repair, enhancing Rib4 activity in some yet undocumented way.

Pyc1 is a pyruvate carboxylase cytoplasmic enzyme that converts pyruvate to oxaloacetate (Morris, 1987). In our dataset, Pyc1 showed an inconclusive SP in WT, and a high confidence score in *rpb9Δ*. It has been shown that deletion of the gene coding Pyc1 causes no change in phenotype. However, the absence of both Pyc1 and Pyc2, another pyruvate carboxylase, prevents yeast from metabolizing glucose (Stucka, 1991). Pyc2 showed no significant interaction with Rpb3 in our data.

It is unclear why Pyc1 would interact with Rpb3 in the absence of Rpb9. There are no previously documented interactions with Rpb3, and very little in the existing literature links Pyc1 to transcription. The best model for this phenomenon involves the prolyl isomerase Ess1. Ess1 is an isomerase that acts on the CTD of Rpb1 to regulate transcription (Wu, 2000). Exx1

primarily isomerizes the Ser5-Pro6 bond of the CTD heptapeptide when Ser5 is phosphorylated (Gemmill, 2005). Such conformational changes have been shown to affect Pol II cofactor binding, and appear to also indirectly effect chromatin modification (Ma, 2012). It is possible Pyc1 is part of a feedback chain involved in this regulation, but the relationship between Pyc1 and Ess1 is not clear. Likewise, as Ess1 scored as inconclusive in our data set, it is uncertain Ess1 interacts with Pol II in the absence of Rpb9.

Tgl4 is a triacylglycerol lipase involved in metabolism of lipid particles (Athenstaedt, 2005). Tgl4 has been shown to exhibit a large range of activities, including TAG lipase, steryl ester hydrolase, phospholipase A(2) activities, and catalyzes the acyl-CoA-dependent acylation of lysophosphatidic acid to phosphatidic acid (Rajakumari, 2010). Tgl4 showed no interaction in WT, and a high confidence score in the *rp9Δ* strain. Speculation on why this protein shows a novel interaction with Rpb3 after deletion of Rpb9 is difficult. There are no documented interactions between Tgl4 and any Pol II subunit. Cdc28, a subunit of cyclin dependent kinases (CDK), has been found to interact with both Tgl4 and Rpb1. Phosphorylation of Tgl4 by Cdk1 has been shown to lead to budding during G1 phase (Kurat, 2009). This finding suggests Tgl4's interaction with Rpb3 may alter cell replication to compensate for the loss of Rpb9-related DNA repair.

Hxk1 phosphorylates glucose to begin metabolism of the sugar. Hxk1 shares this activity with hexokinase isoenzyme 2 (Hxk2), a paralog (Lobo, 1977). Hxk2 is the primary sugar hexokinase for fermentable sugars (De Winde, 1996). Hxk1, meanwhile, is most active when yeast is grown on non-fermentable carbon sources. Hxk2 has been shown to enter the nucleus to repress Hxk1 transcription, but Hxk1 has only been documented in the cytosol (Rodriguez, 2001). Hxk1 showed no evidence of interaction in the WT sample, and scored as high

confidence in *rpb9Δ*. The reason for this change in Hxk1's interaction with Rpb3 in the absence of Rpb9 remains unclear.

Both Sec61 and Erv25 are involved in transporting proteins into the endoplasmic reticulum, and show an increase in SP from an inconclusive score in WT to a high confidence score with the deletion of *rpb9*. Neither of these proteins have shown any interaction with Pol II previously. Sec61 is the largest part of a transmembrane complex called the Sec 61 complex, or translocon, located in the ER (Deshaies, 1987). In yeast, the Sec61 complex is the primary ribosomal docking port of the ER, through which proteins are translocated into the ER (Prinz, 2000). Misfolded secretory proteins are likewise transported out of the ER via this channel in competition with translocation into the ER (Kalies, 2005).

Erv25 is a member of the p24 family of vesicle coat proteins involved in ER to Golgi transport (Belden, 1996). Erv25 forms a heterotrimer with Erp1, Erp2, and Emp24 (Belden, 1996; Marzioche, 1999). However, none of these three proteins show significant interaction with Rpb3 in our dataset. Deletion of Erv25 shows a decrease in ER retention of misfolded proteins, resulting in more poorly functioning proteins being passed into the Golgi apparatus and potentially adversely affecting the cell (Copic, 2009).

The increase in interaction of both these proteins with Rpb3 in the *rpb9Δ* strain may be due to an unknown signaling network between Pol II and these transport proteins. It is possible the transcription mechanism is alerting the transport system to problems in transcription, which will result in error-containing proteins that will need to be sequestered and dismantled.

Sla1 binds to cytoskeletal proteins, and has been shown to be necessary for the formation of the cortical actin cytoskeleton (Holtzman, 1993). Deletion of *SLA1* has been shown to disrupt formation of the cortical actin cytoskeleton (Holtzman, 1993). In addition, Sla1 appears to have

an active role in endocytosis (Warren, 2002; Howard, 2002). Nuclear uptake of Sla1 is required for this function (Gardiner, 2007).

In this dataset, Sla1's SP increased from displaying no evidence of interaction to a score of high confidence. Interestingly, while Sla1 has no documented interactions with Pol II subunits, when used as a bait protein, Sla1 has pulled down Sen1 (Tonikian, 2009). Sen1, as noted previously, is a RNA/DNA helicase that has been linked to transcription termination, and also shows an increased interaction with Pol II in the absence of Rpb9. The interaction between Sla1 and Sen1 has not yet been investigated, but in the future may contribute to explaining Sla1's interactions with Rpb3 in the absence of Rpb9.

Bbc1 binds type 1 myosin (Tong, 2002). Like Sla1, Bbc1 localizes to actin patches, and appears to have a role in cytoskeletal regulation (Mochida, 2002). Deletion of the *bbc1* gene has been shown to increase the rate of endocytosis, suggesting this gene negatively regulates the process (Kaksonen, 2002). Despite having no previously documented interactions with Pol II, Bbc1 show a significant increase in interaction with Rpb3 when Rpb9 is deleted. It is possible this is due to transcription related signaling to adjust different endocytic pathways to compensate for the loss of transcription fidelity and DNA repair.

Ubp15 showed a large increase in SP, going from no interaction in WT to SP=0.89 in  $\Delta rpb9$  cells, a high confidence score. A deubiquinating protease, deletion of the gene coding for this protein has been shown to slow cell growth significantly (Amerik, 2000). This is likely due to a delay of the start of DNA replication during G2 phase caused by the deletion (Ostapenko, 2015). The interaction with Pol II may be meant to create a similar delay, to give DNA repair mechanisms additional time to compensate for the loss of Rpb9-related repair. Ubp15 has shown no previous interactions with Pol II.

Vtc4 is a vacuolar transport protein that showed an increase in interaction with Rpb3 when Rpb9 was deleted. Vtc4 is a vacuolar membrane polyphosphate polymerase and a subunit of the vacuolar transporter chaperone (VTC) complex (Chohen, 1999). Vtc4 plays a role in the fusion of vacuoles to the cell membranes (Müller, 2002). This protein has been shown to increase in abundance during DNA replication stress (Tkach, 2012). Vtc4's interaction with Pol II is likely linked to this finding, due to the loss of transcription linked DNA repair caused by the deletion of Rpb9. This is another novel interaction, as Vtc4 has no other documented interactions with Pol II.

Tfb2 interaction with Rpb3 is not present in the WT, but scored as high confidence in the absence of Rpb9. Tfb2 is a subunit of TFIIH essential for nucleotide excision repair function of TFIIH (Feaver, 1997). We found no other interaction between Rpb3 and the other TFIIH subunits in our data. Tfb2 has previously been shown to interact with Rpb7 (Duran, 2013). Tfb2 also interacts directly with Tfb5, another subunit of TFIIH (Kainov, 2010). Tfb5 has been linked to global genomic nucleotide excision repair (GG-NER), a process independent of the Rpb9-mediated transcription coupled nucleotide excision repair (TC-NER) (Ding, 2007). The novel interaction between Tfb2 with Rpb3 may be a form of up regulation of GG-NER to compensate for the loss of TC-NER due to the deletion of Rpb9.

Mtd1 is an NAD-dependent 5,10-methylenetetrahydrofolate dehydrogenase, which is a vital precursor to a number of metabolites, such as purines (West, 1993). Unlike the above proteins, deletion of Rpb9 caused a loss of a detectable interaction between Mtd1 and Rpb3, with the SP dropping from near certain to no evidence of interaction. This may be due to a change in need for nucleotides caused by altered DNA replication and transcription rates. Deletion of *rpb9* has previously been shown to cause increased sensitivity to mycophenolic acid, an inhibitor of GMP synthesis, implying there is some link between that pathway and Rpb9 (Desmoucelles, 2002).

There is a final result worth discussing. *Dst1*, more often referred to as TFIIIS, is a transcription factor known to coregulate transcription elongation with Rpb9 (Hemming, 2000). TFIIIS showed an SP of 0.69 in WT, which dropped to an SP of 0.33 in *rpb9Δ*. While both of these results are classified as “inconclusive” under this works metrics, this is due to fairly strict standards for significant hits. SP=0.69 is still a very high probability of interaction, and combined with the drop to SP=0.33 implies a definite change in TFIIIS’s interaction with Pol II. High-copy expression of *dst1*, the gene coding TFIIIS, partially suppressed the 6-azauracil sensitivity of *rpb9Δ* (Hemming, 2000). From this we would expect to see an increase in TFIIIS interaction with Pol II as a compensation for the loss of Rpb9. Instead we see the opposite. It is possible that this is due to a loss of TFIIIS interaction sites within Pol II. Physical interactions between TFIIIS and Rpb9 have been heavily documented, and so it is possible Rpb9 is a primary interaction point between TFIIIS and Pol II (Krogan, 2006. Tarassov, 2008. Schlect, 2012). However, Rpb1, Rpb3, Rpb5, and Rpb11 have also shown interactions with TFIIIS (Krogan, 2004, 2006). These subunits may allow for a reduced number interactions between Pol II and TFIIIS, especially in a high-copy number environment as investigated in Hemming, et al (2000).

The classification of TFIIIS as an inconclusive hit is problematic. This is a result that aligns with the current models for Rpb9 function. The classification scheme of the SAINT results in this work may be too strict, and risks wasting potentially promising hits. Moving forward, it would be worthwhile to examine our results for hits for proteins that have been associated with Rpb9, and which have SPs slightly below the “high confidence” threshold.

## CONCLUSION

Pol II's transcription of mRNA is one of the most heavily studied processes in eukaryotic biochemistry. However, due to Pol II's complexity, many of the interactions between the actors in this process are still poorly understood. This work endeavored to uncover new avenues of research within this area, focusing on Rpb9's effects on the Rpb3 interactome, and by extension the entire interactome of Pol II.

These experiments generated bioinformatics hits that could be pursued in future studies. To be useful, these results would need to show both a high probability of interaction in one strain and a large change in SP between the strains. Fifteen such hits were found in this dataset. Fourteen of these showed strong interactions only in the *rpb9Δ* strain, while only Mtd1 was found to interact significantly with Pol II in only the WT strain. This can be attributed to the loss of Rpb9 from the Pol II complex causing a significant amount of stress the cell must compensate for, requiring the activation of additional signaling pathways.

The goal of this work was not to generate any definitive models. The pairing of MudPIT and SAINT is not a high resolution tool. This toolset is instead useful for the volume of data that it can generate and analyze. This work is a preliminary step towards a number of other studies that will expand upon the interactions discovered here.

## APPENDIX 1: SAINT Table

Included below for the sake of completeness is the full table of SAINT results, listed in alphabetical order by the gene coding for the protein, and including the protein ID and SAINT scores (SP) for both the wild type and *rpb9Δ* samples.

## CURICULUM VITAE

Eric A Talbert

### Education

#### **Master of Science in Biochemistry and Molecular Biology**

Indiana University, Indianapolis, IN

Thesis: Changes in the Rpb3 Interactome Caused by the Deletion of *rpb9* in *Saccharomyces Cerevisiae*

#### **Bachelor of Science in Microbiology**

Purdue University, West Lafayette, IN

#### **Bachelor of Science in Biochemistry**

Purdue University, West Lafayette, IN

Minor in Chemistry

### Professional History

#### **Volunteer Coordinator**

Wildfire, LLC

December, 2015-Current

- Assist Head of Organized Play in scheduling gameplay events for conventions
- Act as liaison between convention volunteers and core management
- Run gameplay events to showcase products during conventions
- Take part in and assist in directing discussion during weekly online product testing meetings

#### **Starts Technician/Quality Assurance and Food Testing Technician**

Vivolac Cultures Corporation

October 2012-September 2013

- Prepared inoculum daily for production tanks from frozen and freeze dried seed
- Maintained the Vivolac library of frozen seed cultures
- Tested both internally produced and independently submitted samples for contamination

#### **Chromatography Chemist**

Cogent, LLC

October 2011- May 2012

- Performed flash chromatography and HPLC purification in support of medicinal chemists developing novel molecules
- Determined identity of purified samples using LC/MS analysis.

#### **Undergraduate Intern**

NOX Technologies, Inc.

January 2011-May2011

- Performed spectrophotometry to assay activity of protein arNOX

**Undergraduate Research Assistant**

Purdue University Department of Medicinal Chemistry and Molecular Pharmacology

August 2007-June 2009

Under Dr. D. James Morr , West Lafayette, Indiana.

Summer 2008 paid for by Howard Hughes Undergraduate Internship.

- Prepared HeLa cell microsome supernatant using centrifugation
- Performed gel electrophoresis, Western blotting and HPLC

**Other Awards**

Howard Hughes Undergraduate Internship (2008)

Eagle Scout (2005)
