FINANCIAL SUPPORT STATEMENT

This investigation was funded by the National Institutes of Health and National Institute on Alcohol Abuse and Alcoholism U01- AA018389. The funds were used for recruitment of participants, including researcher/nurse time, data and sample collection, and genotyping.

Further support came from grants from the Swiss National Funds (SNF no. 310030_169196) and the Swiss Foundation for Alcohol Research (SSA) for FS, and from National Health & Medical

Research Council (NHMRC)/Medical Research Future Funds (MRFF) Practitioner Fellowship (APP1155320) for PH. We confirm the independence of researchers from funders and that all authors, external and internal, had full access to all the data (including statistical reports and tables) in the study and take responsibility for the integrity of the data and the accuracy of the data analysis.

Accepted Article

Abstract

Only a minority of heavy drinkers progress to alcohol-related cirrhosis (ALC). The aim of this study was to identify common genetic variants that underlie risk for ALC. We analyzed data from 1,128 subjects of European ancestry with ALC and 614 heavy drinking subjects without known liver disease from Australia, the United States, the United Kingdom and three countries in Europe. Genome-wide association study (GWAS) was performed, adjusting for principal components and clinical covariates (alcohol use, age, sex, BMI, diabetes). We validated our GWAS findings using UK Biobank. We then performed a meta-analysis combining data from our study, the UK Biobank, and a previously published GWAS. Our GWAS found genome-wide significant risk association of rs738409 in *PNPLA3* (Odds Ratio (OR)=2.19 (G allele), p-value=4.93x10⁻¹⁷) and rs4607179 near *HSD17B13* (OR=0.57 (C allele), p-value=1.09x10⁻¹⁰) with ALC. Conditional analysis accounting for the *PNPLA3* and *HSD17B13* loci identified a new protective association at rs374702773 in *Fas Associated Factor family member 2 (FAF2)* (OR=0.61 (del(T) allele), p-value=2.56x10⁻⁸) for ALC. This association was replicated in the UK Biobank using conditional analysis (OR=0.79, p-value=0.001). Meta-analysis (without conditioning) confirmed genome-wide significance for the newly identified *FAF2* locus as well as *PNPLA3* and *HSD17B13*. Two other previously known loci (*SERPINA1*, *SUGP1/TM6SF2*) were also genome-wide significant in the meta-analysis. GeneOntology pathway analysis identified lipid droplets as the target for several identified genes. In conclusion, our GWAS identified a new locus at *FAF2* associated with reduced risk of ALC among heavy drinkers. Like the *PNPLA3* and *HSD17B13* gene products, the *FAF2* product has been localized to fat droplets in hepatocytes. Our genetic findings implicate lipid droplets in the biological pathway(s) underlying ALC.

Chronic alcohol use is a leading cause of cirrhosis in the Western world and is on the rise in many other countries. Although chronic and heavy alcohol use is a requirement for development of alcohol-related liver cirrhosis (ALC), only a minority of heavy drinkers progress to cirrhosis. Reliable risk estimates for cirrhosis among heavy drinkers are difficult to obtain, but it is often estimated at 10-15% after decades of heavy alcohol use (1, 2). Generally accepted risk factors for the development of ALC include duration and amount of alcohol consumed, female gender, and obesity.

Many authors have suggested genetic variation in vulnerability to alcohol-related, or other types of liver disease. The most reported genetic variant in liver diseases is rs738409 in *PNPLA3*. The variant's G allele is associated with increased risk for non-alcoholic fatty liver disease/steatohepatitis (NAFLD/NASH) (3) and with increased risk and severity for alcohol-related liver diseases (4-6). A genome-wide association study (GWAS) of ALC, from two cohorts comprising approximately 700 alcohol-related cirrhotic cases and 1400 drinking controls without known liver disease, reported a genome-wide-significant association between rs738409 and ALC (7). These investigators also reported association of rs58542926 (*TM6SF2*), and rs641738 (*MBOAT7*) with ALC (7). Additionally, Abul-Husn et al. reported an association between rs72613567 (*HSD17B13*) and alcohol-related and non-alcoholic fatty liver-related cirrhosis (8), although not at a genome-wide significance level. Most recently, Emdin et al. reported an association between rs2642438 (*MARCI*) and all-cause cirrhosis, including in a subset of patients with alcohol-related liver diseases (9). Thus, several analyses have identified Single Nucleotide Polymorphisms (SNPs) associated with both alcohol-related liver disease and

NASH, supporting a genetic predisposition for ALC, as well as shared genetic susceptibility with NASH (10).

We undertook a multinational GWAS of European ancestry participants with carefully characterized ALC status to identify predisposing genetic factors. We enrolled subjects at high and low ends of the spectrum of alcohol-related liver disease, specifically excluding subjects with intermediate stages of disease to maximize statistical power. Cases had a history of high-risk alcohol intake with clinically or histologically defined ALC. Controls were heavy drinkers without clinical evidence of liver disease. We chose drinkers without known liver disease rather than non-drinkers as controls to avoid the potential of finding genetic risk loci related to alcohol use. Our stringent eligibility criteria for this case-control design allowed for standardization of both the ALC subjects and of the non-liver disease subjects across enrollment sites.

Material and Methods

SUBJECTS

GenomALC cohort

The GenomALC study participants were recruited at clinical sites in Australia, France, Germany, Switzerland, the United Kingdom, and the United States using a standardized pre-defined protocol (11). Enrollment occurred between 2012 and 2017 with approvals from site-specific governing ethics committees and written informed consent from all recruited participants. All participants were required to have alcohol consumption of ≥ 80 grams per day (males) and ≥ 50 grams per day (females) for at least 10 years. Controls were defined as having normal bilirubin, AST, and ALT levels at the time of heavy alcohol use and no prior evidence of liver injury.

Those with mildly elevated liver tests were included as controls if their transient elastography was less than 6 kPa. Cases were defined by 1) clinically evident portal hypertension or decompensated cirrhosis (e.g., ascites, esophageal varices), 2) Fibroscan stiffness >22kPa if AST <100 IU/L/>32kPa if AST 100-200 IU/L/exclude if AST >200 IU/L, or 3) liver histology (Metavir score of F4) on a previously-performed liver biopsy. Those with other causes of liver disease (e.g. viral hepatitis, hemochromatosis) or with HIV were excluded as described in detail previously (11). DNA was obtained from blood samples and genotyped on Global Screening Array v1.0 (Illumina., 5200 Illumina Way, San Diego, CA 92122). Genotype data were reviewed using the steps detailed in the Supplemental texts. In brief, using a GWAS data cleaning pipeline, genotyped SNPs were filtered for call rate, violation of the Hardy-Weinberg equilibrium (HWE) and minor allele frequency (MAF). Samples were checked for genotyping rate, sex, relatedness, and European genetic ancestry. PLINK was used to check for discordance between reported and genetic sex, sample relationship was calculated using --genome command and using Pi-hat value, we removed one sample from each pair of related individuals down to second-degree relatives. Genetic ancestry was determined using SNPRelate package using 1000 Genomes Project as reference. Additional genotypes were imputed using the Michigan Imputation Server (12). Additional details on GWAS data cleaning is available in the Supplement Texts under ‘Genetic Data Cleaning’ section.

Laboratory of Neurogenetics (LNG) cohort

Genotype and phenotype data from 860 heavy-drinking subjects who had given consent as part of two NIH screening/natural history protocols (98-AA-009; 05-AA-0121) were provided by the Laboratory for Neurogenetics (LNG) at the National Institutes on Alcohol Abuse and Alcoholism (NIAAA, Rockville, MD, USA) as additional heavy drinking controls. Participants

were required to have alcohol consumption of ≥ 80 grams per day (males) and ≥ 50 grams per day (females) and excluded if they had a serious medical condition requiring ongoing treatment, including liver disease. Genotype data (Illumina OmniExpress Bead Chip) were cleaned and imputed using the same pipeline used for GenomALC. After filtering, 235 participants meeting the inclusion criteria were included as controls.

UK Biobank cohort

Data from the UK Biobank (<https://www.ukbiobank.ac.uk/>) were accessed under approval number 18870. Cirrhosis cases (n=530) were defined as having ICD10 code K70.3; ‘Alcoholic Cirrhosis of Liver’, or ICD-9 code 571.2, ‘Cirrhosis, liver, alcoholic’, and ICD10 code K70.1; ‘Alcoholic hepatitis without ascites’ or ICD-9 code 571.1, ‘Acute alcoholic hepatitis’. Controls (n=10,222) were defined as having 1) reported alcohol intake of ≥ 80 g/d (males) and ≥ 50 g/d (females) and/or 2) an ICD10 diagnosis of F10 (Mental and behavioural disorders due to alcohol), but with no recorded diagnosis of any liver disease. Genotype data were cleaned and imputed by the UK Biobank investigators; we used the ‘White British’ ancestry subset of samples provided. After additional data cleaning (see Supplemental Text), 8,185,141 SNPs in 439 alcohol-related cirrhosis cases and 8,364 controls were available for analysis.

Additional sample description and genotype data cleaning information for the three cohorts is available in the Supplemental Texts.

STATISTICAL METHODS

Genome Wide Association Tests in GenomALC

A total of 1,128 ALC cases and 614 heavy drinking controls were available for analysis. To test association between each SNP and ALC (cases vs. controls), logistic regression between case-control status and dosage value of each SNP was tested using PLINK (13). The following covariates were included in each regression model: 1) first ten principal components (PCs), 2) age, 3) sex, 4) years of excessive drinking, 5) alcohol consumed measured in grams per day, 6) total lifetime alcohol consumed measured in kilograms, 7) diabetes status (present/absent), and 8) body mass index (BMI). To identify additional genetic associations beyond the two genome-wide significant loci (rs4607179 for *HSD17B13* and rs738409 for *PNPLA3*), we ran a conditional GWAS that included minor allele counts (dosage) for variants at the two loci as covariates. Conditional GWAS also included all covariates used in the primary GWAS along with the two dosage values. The p-value threshold for genome-wide statistical significance was set at 5×10^{-8} .

GWAS in UK Biobank data

The data were analyzed with FaST-LMM (14), a mixed model method that computes a kinship matrix to adjust for relatedness/population stratification and infers any missing genotypes at a SNP based on the genotypes of other samples at that SNP. Cases (231) and drinking controls (8,364) that had all the clinical covariates (age, sex, type 2 diabetes mellitus (T2DM) status, BMI, and current daily alcohol intake (in grams)) were included in a GWAS that mirrored the primary analysis performed in GenomALC cohort. To mirror the GenomALC conditional analysis in the UK Biobank data, cases and drinking controls used above were re-analyzed with

the minor allele counts at rs738409 and rs4607179 as covariates along with the clinical variables.

ORs were obtained from logistic regression in PLINK including all relevant covariates, and confidence intervals were calculated from back-transformation of FaST-LMM p-values and PLINK ORs.

As a sensitivity analysis, we also conducted a GWAS of cases and controls that excluded those that did not meet the criteria of current alcohol intake per day ≥ 80 g/day (males) and ≥ 50 g/day (females), resembling the GenomALC criteria. This GWAS included a total of 231 cases and 5,361 controls and adjusted for the same set of covariates used in the primary GWAS.

Meta-analysis

Meta-analysis of our primary GWAS results from GenomALC, the UK Biobank, and the GWAS summary statistics from a published GWAS of ALC (7) was conducted using METAL (15) with genomic control option. Summary statistics for the published GWAS (7) were obtained from http://gengastro.med.tu-dresden.de/suppl/alc_cirrhosis/.

Gene-set enrichment analysis

We used enrichment analysis (16) from Gene Ontology (17, 18) to identify potential pathways shared by genes identified in our GenomALC GWAS analysis. Using the genes that includes or are nearby the SNPs with p-values less than 5×10^{-6} from our primary GWAS analysis, we identified 15 genes for enrichment analysis. We performed enrichment analysis for molecular function, cellular component, and biological processes from Gene Ontology (17, 18).

Results

PRIMARY GWAS ANALYSIS

The primary GenomALC GWAS analysis identified two genome-wide significant associations (Figure 1, Supplementary Figure S1). rs738409 on chromosome 22 (chr22), located in *PNPLA3*, was significantly associated with increased risk of ALC, with a p-value of 4.93×10^{-17} and an OR of 2.19 (95% confidence interval (CI), 1.81 - 2.54) for each copy of the G allele. rs4607179 on chr4, located near *HSD17B13*, was associated with lower risk of ALC with a p-value of 1.09×10^{-10} and OR of 0.57 for each copy of the C allele (95% CI, 0.48 - 0.62) (Table 1). A list of all SNPs with p-values less than 5×10^{-6} and their association test results are shown in Supplementary Table S1. Age, sex, and 10 PCs adjusted GWAS analysis result of GenomALC and additional controls from LNG is shown in Supplementary Figure S2 and Table S2. Descriptive statistics of the GenomALC cohort are shown in Table 2 and UK Biobank and LNG are shown in Table S3. Primary GWAS analysis results from UK Biobank and sensitivity analysis, performed on controls reporting current alcohol use >80/50 grams/day are shown in Supplementary Tables S4 and S5, respectively.

CONDITIONAL GWAS ANALYSIS

To identify additional genetic associations, we performed a conditional GWAS that included minor allele counts (dosage) for variants in the two genome-wide significant loci (rs4607179 for *HSD17B13* and rs738409 for *PNPLA3*) from the primary GWAS analysis as covariates along with the previously included covariates. The conditional GWAS analysis identified genome-wide significant association for rs374702773 (*FAF2*) on chr5 with a p-value of 2.56×10^{-8} and an OR of 0.61 (95% CI, 0.51 - 0.73) for each copy of the 7bp deletion allele (Figure 2, Supplementary

Figure S3, Table 1). Association test results for both primary and conditional GWAS analyses for the *FAF2* locus from GenomALC are shown in Supplementary Table S6. Figure 3 shows a LocusZoom (19) plot of rs374702773 and nearby variants. rs374702773 was not available in the UK Biobank data, instead we tested four variants in strong LD ($D' \geq 0.9$ & $r^2 \geq 0.6$) with it. Linkage disequilibrium (LD) values among variants are shown in Supplementary Table S7. In the conditional analysis of the UK Biobank, rs11134977 showed the strongest association with ALC (OR=0.79, p-value of 0.001), other SNPs (rs11027, rs12514451, rs34152523) in LD with rs374702773 showed similar OR and p-value. (Supplementary Table S6). We tested for interaction between *FAF2* locus (rs374702773 and 4 SNPs in LD) and *PNPLA3* (rs738409) and *FAF2* locus and *HSD17B13* (rs4607179) in GenomALC. None of the interaction terms were statistically significant (p-values >0.44) (Table S8).

META-GWAS OF THREE STUDIES

Meta-analysis of results from GenomALC, UK Biobank, and a previously published GWAS of alcohol-related liver cirrhosis (7) identified five independent genome-wide significant associations with ALC (Figure 4, Supplementary Figure S4). Summaries of top associated SNPs from each locus are shown in Table 1 and all SNPs with p-values less than 5×10^{-6} are shown in Supplementary Table S9. In the meta-analysis, the most significant association at *FAF2* was for rs11134977 (p-value = 1.56×10^{-8}), which is in LD with rs374702773 in *FAF2*. In addition to associations at the *HSD17B13*, *PNPLA3*, and *FAF2* loci, we identified two additional genome-wide significant associations, rs28929474 (chr14:94,844,947, *SERPINA1*, OR 1.90, 95% C.I. 1.52-2.38, p-value= 1.99×10^{-8}) and rs10401969 (chr19:19,407,718, *SUGPI*, OR 1.49 95% C.I. 1.31-1.70, p-value 2.40×10^{-9}) (Table 1). LocusZoom plots of these five loci are available in

Supplementary Figure S5. Meta-analysis of Age, sex, and 10 PCs adjusted GWAS in GenomALC+LNG and UK Biobank and published GWAS from Buch et al. cohorts is available in Supplementary Figure S6 and Table S10.

GENE ENRICHMENT ANALYSIS

Gene enrichment analysis for biological process and cellular component showed a significant enrichment for lipid droplet and its organization among the 15 genes (Supplementary Table S11). Enrichment for biological process was observed for lipid droplet organization (>100-fold, FDR=0.003) and cellular component (>70-fold, FDR=0.020) (Table 3).

Discussion

This is the largest-to-date GWAS for alcohol-related cirrhosis, and the only multi-center GWAS of prospectively enrolled subjects meeting strict, protocol-defined criteria for heavy drinking, and for alcohol-related cirrhosis or no known liver disease. We also conducted the first GWAS meta-analysis in ALC contrasting clinically defined groups of cases and heavy drinking controls from GenomALC, the UK Biobank, and a previously published GWAS on ALC (7). We report a new genome-wide association with ALC; rs374702773 located in *Fas Associated Factor family member 2 (FAF2)*, with the C (minor) allele showing a protective effect. Additionally, we replicated the association between rs738409 (*PNPLA3*) and ALC (7) strengthening previous reports (8, 20). We also replicated an association between *HSD17B13* locus and ALC by identifying a genome-wide significant association between ALC and rs4607179 (p-value=1.09x10⁻¹⁰). Meta-analysis also identified two additional genome-wide significant associations; rs28929474, a missense variant in *SERPINA1* and rs10401969 located in a linkage

disequilibrium block that spans multiple genes including *SUGPI* and *TM6SF2*. However, we did not find genome-wide significance for rs641738 or any other SNPs in *MBOAT7* (primary GWAS p-value=5.31x10⁻⁰³, meta-analysis p-value=4.03x10⁻⁰⁵) which was reported by Buch et al (7). A recently reported association of rs2642438 in *MARCI* gene and cirrhosis (9) was also not genome-wide significant in our meta-analysis (OR=0.81, p-value=7.54x10⁻⁰⁶) nor in GenomALC GWAS (OR=0.79, p-value=0.006), but the effect was in the same direction.

FAF2 represents a novel locus affecting genetic risk for ALC. This association became genome-wide significant for rs374702773 in our GenomALC cohort after accounting for the effects of rs738409 (*PNPLA3*) and rs4607179 (near *HSD17B13*) (Supplementary Table S6). We also replicated this association using UK Biobank cohort (OR=0.79, p-value=0.001 for rs11134977).

Using the larger sample size available in the meta-analysis of GenomALC, UK Biobank, and Buch et al (7), this association was found without conditional analysis (OR=0.79, p-value=1.56x10⁻⁰⁸ for rs11134977). We did not observe interaction between *FAF2* locus and *PNPLA3* or *HSD17B13* loci (Supplementary Table S8). Although this may indicate that these loci act independently, our study was not powered enough to detect interactions. These variants in *FAF2* are in strong LD and represent the same association. Also known as UBDX8, *FAF2* is a sensor of intracellular levels of long-chain unsaturated fatty acids (21). In the presence of unsaturated fatty acid, UBDX8 binds to adipose triglyceride lipase (*ATGL*), the major triglyceride hydrolyzing enzyme, and dissociates it from its activator α/β hydrolase domain 5 (*ABHD5*, also known as comparative gene identification-58 [CGI-58]). This dissociation from *ABHD5*/CGI-58 inhibits triacylglycerol hydrolysis in lipid droplets (21, 22). This biochemical pathway, that is, binding to *ABDH5*/CGI-58 and inhibiting triglyceride hydrolysis in lipid droplets, is believed to be one mechanism by which *PNPLA3* (I148M) contributes to hepatic

steatosis (23, 24). Thus, *FAF2* fits into the current proposed genetic pathways that affect hepatocyte lipid metabolism. However, *FAF2* also regulates SREBP-1 activation and triacylglycerol synthesis from diacylglycerol (DAG) by DAG acyltransferase (21). The role and molecular function of the *FAF2* associated variant and those SNPs in LD with it, are yet to be explored. Thus, the actual role of *FAF2* in ALC risk will require a better understanding of the pathophysiology of liver injury by *FAF2* and other implicated genes.

Meta-analysis found genome-wide significance for association between rs28929474, a missense variant of *SERPINA1*, and ALC. *SERPINA1* codes for the α -1-antitrypsin (AAT) protein, with rs28929474 (Glu366His) coding for the Z variant of α -1-antitrypsin. The Z variant causes conformational rearrangement of α 1-antitrypsin, affecting its degradation by proteases (25, 26).

Homozygosity for the Z variant of *SERPINA1* leads to AAT deficiency (27, 28) and increased risk for cirrhosis. Although this is a variant with low MAF, there is independent evidence that it contributes to the risk of alcohol-related liver disease and cirrhosis. Heterozygosity of this variant has also been associated with portal hypertension (29) and cystic fibrosis-related liver disease (30). Abul-Husn et al. (8) and Chen et al. (31) reported rs28929474 association with alcohol-related liver disease/cirrhosis and non-alcoholic liver diseases using candidate variant analysis and a GWAS level significance with liver transaminases. Strnad and colleagues reported an association between the Z variant heterozygous carriers and cirrhosis in NAFLD (OR=7.3, $p < 0.0001$) and in alcohol misusers (OR=5.8, $p < 0.0001$) (32). Although none of these associations approached GWAS-level significance, their findings are in the same direction as our report. Taken together, this is a new disease risk associated with the AAT Z-variant gene product as up to now it was thought that AAT-related liver disease only occurs in ZZ homozygotes.

We extended an association between *HSD17B13* (17- β -hydroxysteroid dehydrogenase type 13) locus and liver disease reported previously. Although not at genome-wide significance level, these authors reported that the A allele (minor allele) of rs72613567 showed protective effect against NAFLD and/or alcohol-related liver diseases including cirrhosis and hepatocellular carcinoma (8). However, most recently, another group reported GWAS significance for *HSD17B13* associated with protection against NAFLD (33). In our discovery GWAS of GenomALC we found genome-wide significance for rs4607179 near *HSD17B13*. Our meta-analysis confirmed significance for SNPs in *HSD17B13* and risk for ALC; we observe protective effect of the C allele of rs4607179 on ALC at genome-wide significance level (OR=0.80, $p=1.39 \times 10^{-08}$). Although the detailed biological function of *HSD17B13* is not fully understood, it too is known to be associated with hepatic lipid droplets (34) and circulating triglyceride and high density lipoprotein levels (35, 36), suggesting overlapping mechanisms in ALC and other complex liver diseases.

We replicated the association between ALC and rs738409, which codes for a missense mutation in *PNPLA3*. rs738409 had the strongest statistical association and the highest OR among the genome-wide significant SNPs (OR=2.19, $p\text{-value}=4.93 \times 10^{-17}$). This locus has been associated with risk for NAFLD, alcohol-related liver disease, and HCC in several meta-analyses (37-40). *PNPLA3* is a lipase found on the surface of triglyceride droplets in hepatocytes. The variant *PNPLA3* protein may increase hepatic steatosis by increasing dissociation of ABDH5/CGI-58 from adipose triglyceride lipase, thereby inhibiting the triglyceride catabolism by ATGL (23). In addition, the half-life of the rs738409 variant *PNPLA3* protein on the lipid droplet appears prolonged, extending its ability to inhibit triglyceride hydrolysis (23, 24).

Our meta-analysis found genome-wide significance for rs10401969 near *SUGPI* on chr19 (OR=1.49 for C allele, p-value=2.40x10⁻⁰⁹). rs1041969 has been proposed to modulate activity of 3-hydroxy-3-methylglutaryl-CoA reductase (also known as HMG-CoA reductase), the rate limiting enzyme for cholesterol synthesis. rs10401969 has been reported to show associations with plasma LDL cholesterol level, coronary artery disease, hepatic fat in obese patients (41), and elevated ALT in heavy alcohol drinkers (42), suggesting that *SUGPI* may be directly related to genetic risk for ALC. However, *SUGPI* is part of a locus with multiple genes and this intron variant is in strong LD ($r^2 \sim 0.95$ in Europeans) with variants located in nearby *TM6SF2* (Supplementary Figure S5), a locus which has been associated with ALC (7), NAFLD (43-45), cirrhosis/steatosis/fibrosis among chronic hepatitis C patients (46), and impaired lipid synthesis (47). Thus, it is not clear whether this variant implicates *SUGPI* as a potential underlying gene for risk of cirrhosis or is a marker for *TM6SF2*.

One common thread among our new and replication findings is the involvement of genetic variants in lipid biology, particularly triglyceride metabolism. Enrichment analysis using GeneOntology (17) identified lipid droplet cellular components and lipid droplet organization biological processes among the genes identified by GWAS. The genes involved in the process from our list of candidate genes were *HSD17B13*, *PNPLA3*, and *FAF2*. However, these genes have pleiotropic effects: *FAF2* also regulates SREBP-1 activation and triacylglycerol synthesis (21) while *HSD17B13* has retinol dehydrogenase activity (25). Thus, defining the actual role of these genes in ALC will depend on a better understanding of lipid droplet biology, and other biochemical pathways, in the pathophysiology of liver injury especially for non-alcohol related disease, which shares several underlying genetic factors and pathophysiologic mechanisms (48, 49).

This GWAS has potential limitations. Despite being the largest available cohort for ALC, the size of our sample for a GWAS of common variants imposes a limit on the power to detect associations with weaker effect sizes. Second, although the trend for the odds ratios in the UK Biobank cohort is in the same direction as for GenomALC, the strength of the association was weaker. We suspect the weaker association may be due to the smaller number of cases in UK Biobank and expanded definition of heavy drinking controls in the UK Biobank as compared with GenomALC. Using stricter drinking criteria for controls, in our secondary and sensitivity analysis in the smaller UK Biobank cohort, we observed similar association results (Figure S8).

Overall, we report a new genetic association between *FAF2* and ALC. This locus is functionally linked to two previously reported loci (*PNPNA3* and *HSD17B13*) by a biological pathway that governs lipid droplet organization. We also report increased risk for ALC in heterozygous carriers of the *SERPINA1* Z variant. Taken together, our findings suggest that risk of developing ALC is, in part, related to genetic factors, especially genetic factors regulating lipid homeostasis, and heavy alcohol exposure is a necessary but not sufficient pre-condition for ALC.

Table 1

Genome-wide significant associations from primary GWAS analysis.

Top associations at significant loci from GenomALC GWAS										
Chr	BP	rsID	Type	Gene	Effect allele	Effect allele frequency	N cases/controls	Odds Ratio	L95-U95% C.I.	P-value
4	88,214,144	rs4607179	Intergenic	<i>HSD17B13</i>	C	0.24	1128 / 614	0.57	0.48-0.62	1.09x10 ⁻¹⁰
5§	175,894,130	rs374702773	Intronic	<i>FAF2</i>	del(T)7	0.49	1128 / 614	0.61	0.51-0.73	2.56x10 ⁻⁰⁸
22	44,324,727	rs738409	Missense	<i>PNPLA3</i>	G	0.39	1128 / 614	2.19	1.81-2.54	4.93x10 ⁻¹⁷

Top associations at significant loci from meta-analysis of GenomALC, UKB, and Buch et al.										
Chr	BP	rsID	Type	Gene	Effect allele	Effect allele frequency	N cases/controls	Odds Ratio	L95-U95% C.I.	P-value
4	88,230,100	rs10433937	Intronic	<i>HSD17B13</i>	G	0.25	2071 / 10444	0.78	0.71-0.84	2.85 x 10 ⁻⁰⁹
5	175,904,141	rs11134977	Intronic	<i>FAF2</i>	C	0.46	2071 / 10444	0.79	0.72-0.85	1.56x10 ⁻⁰⁸
14	94,844,947	rs28929474	Missense	<i>SERPINA1</i>	T	0.02	2071 / 10444	1.9	1.52-2.38	1.99x10 ⁻⁰⁸
19	19,407,718	rs10401969	Intronic	<i>SUGP1/TM6SF2</i>	C	0.08	2071 / 10444	1.49	1.31-1.70	2.40x10 ⁻⁰⁹

22	44,340,904	rs2294915	Intronic	<i>PNPLA3</i>	T	0.32	2071 / 10444	2.07	1.89-2.27	1.28 x 10 ⁻⁵³
----	------------	-----------	----------	---------------	---	------	--------------	------	-----------	--------------------------

Chr (Chromosome), BP (Base Position), rsID (reference SNP cluster ID), Type (type of base substitution), effect allele (coded allele), effect allele frequency (allele frequency of the effect allele in GenomALC cohort), N cases/controls (number of cases / number of controls), L95-U95% C.I. (lower and upper 95% confidence interval).

§ The significant result for the chromosome 5 locus in GenomALC GWAS was obtained after including minor allele counts for rs738409 and rs4607179 as additional covariates.

Table 2

Phenotypic values among GenomALC cohort.

	GenomALC Cases	GenomALC Controls
N	1128	614
Age¹, mean	52.3	50.1
(SD)	(8.9)	(9.8)
Sex, N males	848	449
(% males)	(75.2%)	(73.1%)
Diabetes, N yes	232	38
(% yes)	(20.6%)	(6.2%)
Body Mass Index (BMI),	26.4	24.5
mean (SD)	(5.3)	(4.8)
Years of excessive drinking,	24.0	20.8
mean (SD)	(11.2)	(9.1)
Alcohol consumed in grams	160	199
per day, median (Q1, Q3)	(104,240)	(135,273)

Total lifetime alcohol consumed in kilograms, median (Q1, Q3)	1315 (760,2237)	1332 (806,2184)
--	--------------------	--------------------

¹ Age for cases (cirrhosis) is calculated as age at first diagnosis of cirrhosis. Age for controls is age at which they enrolled in this trial.

SD stands for standard deviation. N indicates number of individuals. Q1 is first quartile and Q3 is third quartile. GenomALC Cases are individuals with alcohol-related liver cirrhosis. GenomALC Controls are heavy drinkers that do not have known liver alcohol-related liver injury.

Table 3

Gene Ontology based enrichment analysis results

	Number of known genes in GO	Number of genes in the list	Expected	Fold Enrichment	+/-	Raw P value	FDR
Lipid droplet (cellular component)	81	3	0.04	70.69	+	9.94E-06	0.020
Lipid droplet organization (biological process)	21	3	0.01	> 100	+	2.15E-07	0.0034

Number of known genes in GO (number of genes with annotated function in Gene Ontology database), Number of genes in the list (number of genes from the input list (also see Supplementary Table 10) that have the same annotated function from Gene Ontology), Expected (expected number of genes in the list from a random set of genes with same size as input list), +/- (increase/decrease in enrichment), Raw P value (Fisher's exact test based p-value), FDR (false discovery rate, adjusted p-value after random permutation)

Figure 1

Manhattan plot of primary GWAS analysis of GenomALC. The plot shows significant association of SNPs on chromosomes 4 (*HSD17B13*) and 22 (*PNPLA3*). Vertical axis shows $-\log_{10}$ transformed p-value of each tested SNP after adjusting for age, sex, diabetes (yes/no), BMI, years of excessive drinking, alcohol consumed in grams per day, total lifetime alcohol consumed in kg, and ten principal components. Horizontal solid grey line shows genome-wide significance level ($p=5 \times 10^{-8}$), dotted grey line shows suggestive level ($p=5 \times 10^{-6}$).

Figure 2

Manhattan plot of secondary GWAS analysis of GenomALC. After accounting for minor allele counts (dosage) for variants in rs4607179 near *HSD17B13* and rs738409 in *PNPLA3*, secondary analysis in GenomALC shows significant association of SNPs on chromosome 5 (*FAF2*). Vertical axis shows $-\log_{10}$ transformed p-value of each tested SNP after adjusting for rs4607179, rs738409, age, sex, diabetes (yes/no), BMI, years of excessive drinking, alcohol consumed in grams per day, total lifetime alcohol consumed in kg, and ten principal components. Horizontal solid grey line shows genome-wide significance level ($p=5 \times 10^{-8}$), dotted grey line shows suggestive level ($p=5 \times 10^{-6}$).

Figure 3

LocusZoom plot of rs374702773 and nearby SNPs on chromosome 5. From conditional analysis of GenomALC data we identified a new locus rs374702773 (purple diamond) on Chr 5 associated with ALC and nearby SNPs in linkage disequilibrium.

Figure 4

Manhattan plot of meta-analysis of GenomALC, UK Biobank, and Buch et al. Meta-analysis shows significant association of SNPs on chromosomes 4 (*HSD17B13*), 5 (*FAF2*), 14 (*SERPINA1*), 19 (*TM6SF2/SUGP*) and 22 (*PNPLA3*). Vertical axis shows $-\log_{10}$ transformed p-value of each SNP from meta-analysis including GenomALC and UKB cohort GWASs adjusting for age, sex, diabetes (yes/no), BMI, years of excessive drinking, alcohol consumed in grams per day, total lifetime alcohol consumed in kg, and ten principal components and published results from Buch et al.. Solid grey line shows genome-wide significance level ($p=5 \times 10^{-8}$), dotted grey line shows suggestive level ($p=5 \times 10^{-6}$).
